In a large meta-analysis, Naylor et al. concluded that less than half of CABG patients who suffered perioperative strokes had significant carotid disease, defined as either significant stenosis or occlusion.[4] Naylor et al. also demonstrated that the degree of carotid disease was statistically associated with increasingly high rates of perioperative stroke in CABG patients, which ranged from 3 percent in patients with mild disease up to 7 to 11 percent in patients with carotid occlusion. An extensive retrospective study from our practice at The Johns Hopkins Hospital yielded similar results.[5] However, carotid disease is a fairly specific risk factor for aortic arch atherosclerosis,[6] which is widely believed to be the most important source of arterial emboli in CABG-related strokes. As a result, although the finding of carotid disease clearly increases the risk of perioperative stroke in CABG, it remains unclear whether the link between carotid disease and perioperative stroke is truly causal, since carotid disease alone has never been proven to be an independent risk factor for perioperative stroke while controlling for aortic atherosclerosis. At the same time, there are reports of individuals in whom the finding of preoperative stenosis preceded a "watershed" stroke in the distribution of a stenotic carotid artery.[7] In summary, carotid disease is associated with an increased stroke risk in CABG patients, but less than half of CABG-related strokes occur in patients with carotid disease and it is likely that only a subset of these strokes are due to carotid stenosis per se rather than related conditions.

Although the effect of carotid disease on perioperative stroke risk in CABG remains uncertain, its effect on long-term stroke risk is well documented. Carotid disease is thought to cause between 20 and 30 percent of strokes.[8] With regard to long-term stroke risk, the natural history of carotid disease in CABG patients is presumably similar to that of nonsurgical patients in large prospective studies of carotid stenosis, such as the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and Asymptomatic Carotid Atherosclerosis Study (ACAS).[9,10] No large, prospective, controlled trials to date have specifically addressed the impact of carotid stenosis and/or occlusion or their related therapies on the long-term rates of stroke free survival in CABG patients. A final point to consider is that there is likely a small degree of mechanistic overlap between "long-term" and "perioperative" strokes; there are bound to be CABG patients with carotid stenosis who, by chance, suffer strokes due to carotid plaque rupture unrelated to the operation itself, within the perioperative period.

**TABLE 30-2: Mechanisms of Perioperative Stroke in Coronary Bypass Patients**

| Mechanism of Stroke | % of Perioperative Strokes in Coronary Artery Bypass |
|---|---|
| Embolic | 62.1 |
| Unclassified | 13.9 |
| Multiple etiologies | 10.1 |
| Hypoperfusion | 8.1 |
| Lacunar | 1 |
| Thrombotic | 1 |

## CORONARY ARTERY DISEASE AND MYOCARDIAL INFARCTION ASSOCIATED WITH CAROTID ENDARTERECTOMY

It has long been known that vascular lesions outside the coronary vascular bed can be "index lesions" of MI. Indeed, MI is a well-documented complication of several commonly performed peripheral vascular interventions, such as aortic or infrainguinal procedures. The mechanism is thought to be embolic, as fragments of plaque from the diseased vascular bed are mobilized during surgical manipulation and become lodged in already-stenosed coronary arteries. Nonfatal and fatal MIs remain devastating postoperative complications of CEA, although the incidence of MI in ACAS was less than 1 percent.[11] These numbers seem surprisingly low when one considers that up to 50 percent of patients with carotid disease have some degree of coronary artery disease. Of course, MI rates are likely to be somewhat higher in CABG patients who, by definition, have severe coronary artery disease.

## CAROTID DISEASE IN CORONARY ARTERY BYPASS PATIENTS

Previous studies have reported an incidence of carotid disease in CABG patients ranging from 2 to 22 percent.[5] This range is rather wide because the definition of "significant" carotid disease varies between centers. For example, even ACAS and NASCET stratified their respective cohorts using different numerical thresholds. Specifically, ACAS defined 60 percent luminal stenosis as significant whereas NASCET initially employed a 70-percent threshold that was later changed to 50 percent.[9,10] After ACAS showed a significant but underwhelming clinical benefit for CEA using the 60 percent threshold, numerous follow-up studies have used greater degrees of carotid stenosis as thresholds to trigger surgical intervention. The ambiguity of the term "significant stenosis" is equally apparent in studies of carotid disease in CABG populations, where thresholds have routinely ranged from 50 to 80 percent luminal narrowing.

Regardless of the threshold one chooses to define significant carotid disease, there are several ways to identify and quantify carotid lesions. Ideally, the process begins by including questions in the history designed to identify patients at high risk for carotid disease. Because the etiologies of carotid and coronary artery disease are so similar, it is best to focus on the risk factors that have been validated in previous studies of carotid disease within CABG populations (Table 30-3). On physical examination, the most important finding is the presence of a carotid bruit. Although a carotid bruit is not pathognomonic for carotid stenosis, at our center nearly 40 percent of CABG patients with a bruit had carotid stenosis in excess of 70 percent as measured by carotid duplex ultrasound.[5] In addition, any exam findings indicative of CVD (e.g., focal neurologic deficits) or peripheral vascular disease (e.g., weak distal extremity pulses, popliteal bruits) also greatly increase the likelihood of carotid disease.

For those patients identified as high risk for carotid disease, screening by duplex ultrasound represents a noninvasive means of quantitatively assessing carotid disease. Duplex ultrasonographic measurements are obtained from peak blood flow velocities measured across the proximal internal carotid artery, which are correlated to the gold standard of percentage luminal occlusion derived from digital subtraction angiography. For example, at our institution we use the criteria derived by Grant et al.[12] to translate duplex measurements to percentage luminal stenosis. Equivocal cases are then further evaluated by magnetic resonance angiography and/or CT angiography. With angiography, we define percentage stenosis according to the NASCET criteria: $100 \times (1-S/D)$, where $S$ = diameter at the point of greatest luminal narrowing due to stenosis and $D$ = the luminal diameter in the "normal" portion of the carotid at a point at which the walls are parallel.

It is important to note that different measurement criteria have been used in the past. The European Carotid Surgery Trial used an estimate of the unseen carotid bulb wall in place of $S$.[13] Still another "common carotid method" uses the diameter of the common carotid in place of $S$. Although there are advantages and disadvantages with each method, what matters most is consistency.

**TABLE 30-3: Risk Factors for Carotid Disease in Coronary Bypass Patients**

| Highly Significant ($p$ <0.01) | Significant ($p$ <0.05) |
|---|---|
| Prior CVA | Tobacco use[a] |
| Prior CVD (CVA or TIA)[a] | Left main disease >50 |
| Carotid bruit[a] | Hypertension[a] |
| Peripheral vascular disease | Prior CEA |
| Age >65[a] | |

CVA, cerebrovascular accident; CVD, cerebrovascular disease; TIA, transient ischemic attack.

[a]Shared risk factors for stroke and cerebrovascular disease in coronary artery bypass patients.

## CAROTID INTERVENTION

When a patient is diagnosed with carotid stenosis (i.e., nonocclusive carotid disease), two treatment strategies are available: (1) medical management with antiplatelet therapy and/or cholesterol-lowering agents and (2) CEA or percutaneous angioplasty with or without carotid stenting. The choice of therapy is typically guided by the presence or absence of cerebrovascular symptoms (i.e., prior stroke or transient ischemic attack) and the extent of stenosis based on the results of several large multicenter prospective randomized clinical trials conducted in the 1980s and 1990s.

### Carotid Endarterectomy

NASCET compared CEA to medical management with aspirin and identified a 15 percent absolute reduction in stroke risk (i.e., 25 vs 10 percent) at 2 years in symptomatic patients with carotid stenosis in excess of 70 percent.[9] Further analysis showed a more modest benefit in patients with carotid stenosis in excess of 50 percent.[14] Of the three largest studies on asymptomatic cohorts, the CASANOVA and VA trials found no significant benefit for CEA.[15,16] ACAS identified an absolute stroke risk reduction of just 5 percent (i.e., 10–15 percent).[10] Since the degree of benefit patients receive from CEA is directly proportional to their preoperative stroke risk, many authors have sought to incorporate a variety of risk factors in addition to the degree of carotid stenosis in order to expand indications for CEA to all patients likely to benefit from surgery. Critics of ACAS and NASCET maintain that CEA is now less effective because medical therapies have evolved while the majority of CEAs are now performed by surgeons with higher complication rates than those at the centers of excellence used in the landmark studies. The net result is that CEA is strongly indicated in symptomatic patients with carotid stenosis in excess of 70 percent. The

role of CEA is more controversial in asymptomatic patients with carotid stenosis, but is generally recommended in cases of severe or critical (e.g., 80 percent) carotid disease. It is unknown how these results extrapolate to CABG patients, in whom operative complications such as MI and/or death are likely to be much higher and may even negate the stroke-risk benefits of CEA.

### Carotid Stenting

The past 2 decades have seen a rapid expansion in endovascular intervention for carotid disease. A recent meta-analysis performed by Meier et al. included all published trials comparing stenting to CEA published between January 1990 and July 2009 and found CEA to have better short-term outcomes than CAS, with a significantly higher risk of periprocedural stroke in the CAS group.[17] However, there was no significant difference in intermediate-term outcomes between the two groups, and the CAS group actually had a lower rate of cranial nerve injuries and MIs. Recent data from the large multicenter Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) yielded similar results, demonstrating a higher risk of stroke during the periprocedural period with stenting and a higher risk of MI with endarterectomy.[18] Overall, however, there was no significant difference in the risk of composite primary outcome of stroke, MI or death between the group undergoing CEA and the group undergoing stenting. Long-term outcomes for stenting are also promising, with the results from the randomized trial, Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE), demonstrating a lower rate of carotid revascularization procedures after 1 year in patients receiving stents compared with those who underwent endarterectomy.[19]

In general, recent studies have used the indications for carotid stenting that were based upon the original NASCET and ECST criteria for endarterectomy. As new data emerge comparing carotid stenting to CEA, the threshold for intervention according to risk–benefit analysis will continue to evolve. As was originally seen with the NASCET data, the risks of CEA greatly depended on the skill and experience level of the surgeon; clearly, the same holds true in attempting to calculate the risks of intervention with stenting procedures. The substantial heterogeneity between studies and the various levels of operator skill and experience have made it difficult to compare carotid stenting with CEA. Toward this end, recent emerging data from large multicenter trials, such as the CREST Trial, will provide further guidance and work to change current management algorithms.

## SURGICAL AND INTERVENTIONAL TREATMENT OF COMBINED CORONARY AND CAROTID DISEASE

Surgical treatment for concomitant coronary and carotid disease varies between centers, primarily because there are no large multicenter prospective randomized trials to guide therapy. Consequently, guidance must be pieced together using a combination of data from small studies, meta-analyses and local institutional experience. In our practice, we advocate treating the symptomatic territory (i.e., carotid or coronary) first and reserving combined procedures for those with symptoms in both territories. The reasoning for our recommendation is summarized later. A well performed series of meta-analyses[20–22] of virtually all prior reports published by Naylor et al. has helped inform the practice in recent years.

### Staged Carotid Endarterectomy–Coronary Artery Bypass Grafting

In the staged approach, the carotid lesion is addressed first by CEA, followed by CABG at a later point. The time interval between the procedures has varied in the literature from days to months. The rationale behind this sequence is predicated on a reduction in perioperative stroke risk due to a prophylactic treatment of the carotid lesion. This strategy is most appropriate in patients whose carotid disease is equally or more advanced than their coronary disease, as they must forego CABG for some period of time. Conversely, this strategy is inappropriate for patients with critical coronary stenosis or severe multiple-vessel disease, since the heightened risk of perioperative MI remains unaddressed. Naylor's data[22] on combined procedures to date have shown that perioperative MI is slightly more common than perioperative stroke in patients undergoing staged CAE–CABG (Table 30-4).

**TABLE 30-4: Complication Rates for Patients Undergoing Combined Procedures**

| | Stroke | MI | Stroke/MI/Death |
|---|---|---|---|
| Synchronous CEA/CABG | 4.6 (3.9–5.4) | 3.6 (3.0–4.2) | 11.5 (10.1–12.9) |
| CEA + "Off-pump" CABG | NA | NA | 3.5 (1.6–5.5) |
| CEA–CABG (staged) | 2.7 (1.6–3.9) | 6.5 (3.2–9.7) | 10.2 (7.4–13.1) |
| CABG–CEA (reverse-staged) | 6.3 (1.0–11.7) | 0.9 (0.5–1.4) | 5.0 (0.0–10.6) |
| CAS–CABG | 4.2 (2.4–6.1) | 1.8 (0.5–3.0) | 9.4 (7.0–11.8) |

Data compiled from references 20–22.
Complication rates expressed in percentages.
95% confidence intervals in parentheses.

## Reversed-Staged Coronary Artery Bypass Grafting–Carotid Endarterectomy

In patients whose coronary disease is more critical than their carotid disease, a reversed-staged approach may be appropriate. MI was the most common complication associated with CEA in the ACAS study, and has been shown to occur with greater frequency in patients with unstable angina and coronary artery disease. Patients who have recently undergone CABG have reduced their risk of perioperative MI and are thus thought to be better candidates for subsequent CEA. As one would expect, the results of the reversed-staged approach run are essentially the opposite of those of the staged approach (Table 30-4), with higher rates of stroke than MI.

## Combined Carotid Endarterectomy–Coronary Artery Bypass Grafting

For patients experiencing symptoms of both coronary and carotid diseases, it may be advantageous to operate on both territories simultaneously. Because the prospect of addressing both lesions and their associated complications is so appealing, there have been a disproportionate number of papers studying this combined approach. Various techniques have been demonstrated: (1) CEA prior to opening the thorax, (2) CEA after opening the thorax but prior to cannulation, and (3) CEA while on cardiopulmonary bypass. The first is by far the most popular.

The results of the combined approach have varied widely. In the meta-analyses conducted to date, the incidence of stroke, MI, and death have each been around 5 percent.[22–25] These numbers are likely skewed by the fact that combined procedures are more likely to be offered to sicker patients. At the same time, there are indications that the technical complexity of operating on both territories has poor reproducibility and may even be dangerous when attempted outside centers of excellence. For example, a study of 226 patients treated with concomitant procedures at community-based hospitals demonstrated a combined stroke/mortality rate of 17.7 percent.[26]

## Staged Carotid Artery Stenting–Coronary Artery Bypass Grafting

As published data on CAS have become more positive over the past decade, there have been an increasing number of reports in which CAS has been used in place of CEA in the traditional staged strategy prior to CABG. Naylor's recent meta-analysis of this (admittedly heterogeneous) data revealed comparable rates of perioperative complications as compared with other more traditional forms of combined procedures described earlier, though data on MI were not reported. Given that CAS is less invasive than CEA, this can be seen as a motivation for expanding indications for CAS–CABG in favor of CEA–CABG. One potential complicating factor when considering combining CAS and CABG procedures is the need to balance the benefits of pre- and postprocedural antiplatelet therapy with regard to stent patency against the risk of perioperative hemorrhage related to CABG. However, Naylor et al.[21] report that although data on bleeding complications are available for only a subset of patients who have undergone CAS–CABG, there were apparently only seven instances of major perioperative hemorrhage (0.9 percent), only two of which were fatal (0.3 percent).

## Carotid Endarterectomy—Off-Pump Coronary Artery Bypass Graft

"Off-pump" CABG refers to the technique of performing coronary artery bypass without aortic cross-clamping. Although there is relatively little data on combined CEA and off-pump CABG, preliminary results suggest that this approach is associated with lower rates of perioperative complications than either traditional approaches or those employing CAS (Table 30-4).[20] One possible explanation for this result is that, as stated earlier, the association between carotid stenosis and perioperative stroke in CABG may be an indirect relationship mediated by aortic arch disease. If that is in fact the case, then the low rates of complication in these series may be due to the lack of aortic cross-clamping rather than CEA itself.

# RISK-STRATIFICATION MODELS FOR PREOPERATIVE CAROTID SCREENING PRIOR TO CORONARY ARTERY BYPASS GRAFT

Based on the issues already discussed, carotid intervention (i.e., CEA or stenting) is indicated in only about 5 percent of the total CABG population. Screening all CABG patients for carotid disease with duplex ultrasonography requires significant economic resources, inconvenience to patients, and potential delay to CABG. An alternative approach is to use a selective screening approach based on identified risk factors for carotid disease. At our institution, we selectively screen patients at "high risk" for both carotid disease and stroke: patients with cerebrovascular symptoms, a carotid bruit or age in excess of 65 years. Our algorithm (Fig. 30-1) has a sensitivity in excess of 80 percent and specificity of 40 percent in identifying significant operable carotid disease (>70 percent stenosis), and has reduced screening loads by 40 percent.[5] Furthermore, a post hoc retrospective analysis indicates that all CABG patients evaluated at our center over a 2-year period that were found to have significant carotid disease and suffered perioperative strokes would have been

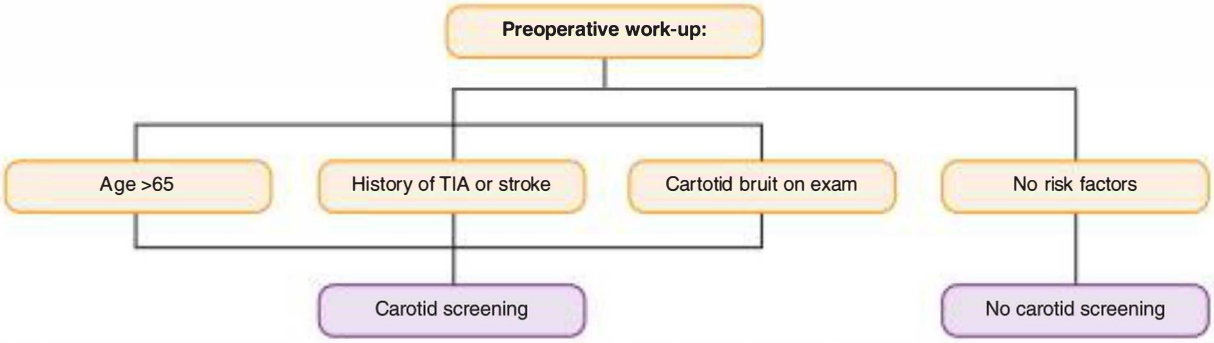

**FIGURE 30-1** Preoperative carotid duplex screening algorithm in use at Johns Hopkins Hospital. (Durand DJ, Perler BA, Roseborough GS, et al. Mandatory versus selective preoperative carotid screening: A retrospective analysis. *Ann Thorac Surg* 2004;78:159–166.)

identified as "high risk" for carotid stenosis according to our selective screening criteria. The incidence of asymptomatic carotid disease in "low-risk" patients that would have gone unscreened was only 5 percent and CEA would only have been indicated in 1 percent of these patients. We advocate this screening algorithm, or one that incorporates additional stroke risk factors (e.g., peripheral vascular disease), to optimize preoperative carotid screening.

## MANAGEMENT OF CONCOMITANT CAROTID AND CORONARY ARTERY DISEASE BOARD REVIEW QUESTIONS (CHAPTER 30)

1. Which of the following is correct regarding perioperative stroke?
   A. More than half of CABG patients suffering perioperative stroke will have significant carotid artery disease.
   B. Carotid occlusion is associated with a stroke incidence of 3 percent after CABG.
   C. The degree of carotid disease is not associated with risk of stroke.
   D. Carotid disease is a risk factor for aortic arch atherosclerosis.
   E. The finding of carotid disease does not increase the risk of stroke.

2. Which procedure has the lowest incidence of stroke?
   A. Synchronous CEA–CABG
   B. CEA, then CABG
   C. CABG, then CEA
   D. CAS–CABG

3. Which procedure has the lowest incidence of myocardial infarction?
   A. Synchronous CEA–CABG
   B. CEA, then CABG
   C. CABG, then CEA
   D. CAS–CABG

4. Which is true regarding outcomes of trials for carotid endarterectomy?
   A. NASCET identified a 15 percent absolute reduction in risk of stroke
   B. CASANOVA demonstrated a stroke risk reduction of 10 percent after CEA
   C. The VA trials showed a stroke risk reduction of 8 percent
   D. ACAS revealed an absolute risk reduction of 20 percent

5. Which is correct regarding carotid stenting compared to CEA?
   A. There is a lower incidence of periprocedural stroke
   B. CEA has improved intermediate-term outcomes
   C. There is a lower incidence of cranial nerve injury
   D. There is a higher incidence of myocardial infarction
   E. There is a higher incidence of carotid revascularization procedures

## ANSWERS

1. **Answer: D.** Carotid disease is a fairly specific risk factor for aortic arch atherosclerosis. Less than half of CABG patients suffering perioperative stroke will have significant carotid artery disease. Carotid occlusion is associated with a stroke incidence of 7 to 11 percent after CABG. Increasing degree of carotid disease is associated with an increasing risk of stroke, and the finding of carotid disease clearly increases the risk of stroke after CABG.
2. **Answer: B.** Staged carotid endarterectomy followed by CABG has the lowest incidence of stroke at 2.7 percent. Staged carotid stenting followed by CABG has a stroke incidence of 4.2 percent, synchronous CEA–CABG has a stroke incidence of 4.6 percent, and staged CABG followed by CEA has a stroke incidence of 6.3 percent.
3. **Answer: C.** Staged CABG followed by CEA has the lowest incidence of MI at 0.9 percent. Staged carotid stenting followed by CABG has an MI incidence of 1.8 percent, synchronous CEA-CABG has an MI incidence of 3.6 percent, and staged carotid endarterectomy followed by CABG has an MI incidence of 6.5 percent.
4. **Answer: A.** The NASCET trial demonstrated an absolute risk reduction of 15 percent in patients with carotid stenosis >70 percent after CEA. Neither the CASANOVA nor the VA trials found a significant benefit for CEA in asymptomatic patients. The ACAS trial showed an absolute risk reduction of 5 percent.
5. **Answer: C.** There is a lower incidence of cranial nerve injury after carotid stenting. There is also a lower incidence of myocardial infarction and carotid revascularization procedures after carotid stenting, but a higher incidence of periprocedural stroke. In general, intermediate-term outcomes are similar between carotid stenting and CEA.

# Mechanical Complications of Myocardial Infarction

*Ryan R. Davies*
*Michael P. Robich*
*Michael A. Coady*

## KEY CONCEPTS

- Epidemiology
  - Six to ten percent of patients develop cardiogenic shock after myocardial infarction.
  - Mitral regurgitation (MR) occurs in 8 to 50 percent of patients after myocardial infarction.
  - Post-infarct ventricular septal defects (VSD) occurs in <0.5 percent of myocardial infarction (MI) patients.
  - Only 24 percent of medically treated patients with post-infarct VSD survive 30 days.
  - In autopsy series, 30 percent of myocardial infarction (MI) is accompanied by ventricular free wall rupture (VFWR).
  - The incidence of left ventricular aneurysms depends on exact definition; 10 to 35 percent of patients will develop region of systolic akinesia or dyskinesia after transmural myocardial infarction (MI).
- Pathophysiology
  - In cardiogenic shock associated with MI, worsening ventricular function leads to decreased coronary perfusion, worsening ischemia, and an enlarging infarct zone.
  - Three primary pathologic mechanisms exist for post-infarct MR:
    - Papillary muscle rupture
    - Acute ischemic MR
    - Chronic ischemic MR.
  - Post-infarct VSD follows large transmural infarction with weakening of the septal wall.
  - Post-infarct VSD results in left-to-right shunt of variable magnitude with diversion of blood flow from systemic to pulmonary circulation and low-cardiac-output state, ultimately into cardiogenic shock.
  - VFWR occurs after large, transmural MI in myocardium without collaterals.
  - Traditionally ventricular aneurysm is defined as region of myocardium exhibiting abnormal diastolic contour with systolic dyskinesia and paradoxic bulging.
  - Ventricular remodeling after large transmural infarct leads to infract expansion and aneurysm formation.
- Clinical features
  - Symptoms of systemic and coronary hypoperfusion, including cold, clammy extremities, cyanosis, oliguria, and altered sensorium.
  - Cardiogenic shock associated with MI leads to pulmonary edema, chest pain, and shortness of breath.
  - New holosystolic murmur best heard at the apex is noted in MR associated with MI.
  - Post-infarct VSD typically occurs 5 to 6 days after MI
  - Eighty percent of VFWR occur within 7 days after infarct.
  - Subacute VFWR results in a worsening pericardial effusion and hypotension without pulseless electrical activity and cardiac arrest.
  - Pseudoaneurysm formation from VFWR occurs approximately 3 months after MI with variable symptomatology.
  - Commonly presents with congestive heart failure
  - LV aneurysm commonly presents with congestive heart failure, angina, and/or dyspnea.
  - Mural thrombus present in 50 percent of ventricular aneurysm patients at surgery.
- Diagnostics
  - Invasive hemodynamic monitoring important in optimizing both coronary and systemic perfusion.
  - Electrocardiography (ECG) confirms cardiac ischemia; chest X-ray rules out pneumothorax.
  - Emergent echocardiography (ECHO) to rule out other mechanical causes of shock, including papillary muscle or ventricular rupture.

- Echocardiography (ECHO) allows evaluation of left ventricular (LV) function and mitral apparatus; can accurately diagnose pulmonary muscle (PM) rupture as well as exclude other mechanical causes of cardiovascular collapse.
- Location of infarct of echocardiography (ECHO) correlates with location of post-infarct VSD.
- ECHO is important to differentiate post-infarct VSD from acute, severe mitral regurgitation (sensitivity and specificity ~100 percent).
- Angiography allows delineation of coronary anatomy, estimation of ventricular aneurysm size, and guided placement of intra-aortic balloon pump (IABP).
- Rapid pericardiocentesis is both diagnostic and therapeutic for VFWR.
- Echocardiography (ECHO) identifies effusion with pericardial clots for VFWR; Doppler evaluation may identify rupture site.
- MRI may be useful in evaluating pseudoaneurysms.

- Treatment
  - Medical
    - No pharmacologic agent has been demonstrated to improve survival for cardiogenic shock associated with acute MI; inotropes/vasodilators/vasopressors should be used to stabilize the patient in preparation for definitive therapy.
    - Thrombolysis is of unproven benefit for patients in cardiogenic shock.
    - Medical therapy for acute MR and papillary muscle rupture is supportive only.
    - Intra-aortic balloon pump counterpulsation (IABP) improves both systemic and coronary perfusion while reducing systemic vascular resistance and left-to-right shunt in post-infarct VSD.
  - Surgical
    - IABP counterpulsation may improve hemodynamic stability in patients who undergo systemic thrombolysis; may improve outcomes in patients with cardiogenic shock; excellent option for hemodynamic stabilization.
    - Clear long-term benefit to percutaneous coronary revascularization in patients with cardiogenic shock (SHOCK trial). Successful angioplasty is associated with significant improvements in 30-day mortality.
    - Emergent CABG improves survival in most studies of cardiogenic shock; optimal indications unclear but important treatment where PCI is unsuccessful or inappropriate.
    - Left ventricular assist device (LVAD) and orthotopic heart transplantation are options when revascularization is not possible or ineffective.
    - Surgical indications for post-MI MR include
      - PM rupture
      - Acute, severe MR not improved by percutaneous coronary intervention or thrombolysis
      - Chronic 3+ to 4+ MR and symptomatic coronary disease
      - Other indications: LVESVI ≥80 mL/m², regurgitant fraction 50 percent greater than forward ejection fraction, estimated regurgitant orifice >20 mm².
    - Multiple repair techniques described for post-infarct VSD, including apical amputation, patch closure, and infarct exclusion
    - Pseudoaneurysm repair primarily by closure of neck or patch repair similar to true aneurysms.
    - Asymptomatic patients with small aneurysms can be managed medically; larger symptomatic aneurysms require operative repair.
    - Multiple ventricular aneurysm repair techniques described: plication, linear repair, variety of geometric repairs.
    - Geometric ventricular aneurysm repairs (Dor, Jatene, Cooley) have advantage of restoring LV geometry and preserving long-term LV function.
- Outcomes and prognosis
  - Hospital mortality rates in patients presenting in cardiogenic shock after acute MI are 60 percent vs 8 percent for those without cardiogenic shock; emergent revascularization improves survival in nearly all patients.
  - Operative mortality in acute severe MR (with or without PM rupture) ~20 percent.
  - Operative mortality remains high for post-infarct VSD (though better than medical therapy alone): 20 to 50 percent.
  - Hospital survivors after post-infarct VSD repair have excellent long-term survival (61 percent at 8 years).
  - Operative mortality approximately 25 percent with only patch repair of VFWR; similar operative mortality for those with pseudoaneurysms.
  - Operative mortality for ventricular aneurysm repair 2 to 13 percent; five-year survival from 20 to 42 percent.
  - Survival after ventricular aneurysm repair (short and long term) is probably lower with geometric repairs than with linear repairs.
  - Measurements of LV function improve after aneurysm repair and maintained long term.

## OVERVIEW

The first clinical description of myocardial infarction (MI) was reported by Herrick in 1912.[1] He concluded from the clinical history that "while sudden death often does occur, yet at times it is postponed for several hours or even days, and in some instances, a complete, that is functionally complete, recovery ensues." In the current era, a complete recovery after an acute MI has become the norm rather than the exception. Unfortunately however, the mortality for some patients remains devastatingly high. In particular, patients with cardiogenic shock after an acute MI have less than a 50 percent chance of surviving their hospital stay.[2,3]

Cardiogenic shock in acute MI may result from a variety of mechanical complications. Most commonly it results from ventricular infarction and dysfunction alone, but other mechanical processes may contribute to the syndrome: ventricular septal rupture (VSR), ventricular free wall rupture, and ischemic mitral regurgitation (IMR).[4] Although surgical therapies for these three conditions have long been recognized, the importance of timely revascularization in patients with cardiogenic shock in the absence of ventricular rupture or mitral regurgitation (MR) has received increased attention recently (see the decision-making flowchart; Fig. 31-1).

The topics covered in this chapter include (1) post-MI cardiogenic shock and ventricular dysfunction, (2) ischemic mitral valve (MV) disease, (3) postinfarction VSR, (4) postinfarction ventricular free wall rupture, and (5) ventricular aneurysms.

# POSTMYOCARDIAL INFARCTION, CARDIOGENIC SHOCK, AND VENTRICULAR DYSFUNCTION

## Introduction

Cardiogenic shock is a clinical syndrome that is characterized by hypotension and systemic hypoperfusion in the setting of ineffective cardiac function. Although the first report of circulatory collapse secondary to MI may have occurred as early as 1794 with Sir Everald Home's description of the life of the British surgeon Sir John Hunter, Herrick first recognized the clinical signs of cardiogenic shock: cold clammy extremities, oliguria, and an altered mental status.[5,6] These clinical signs are accompanied by alterations in hemodynamic parameters: systolic blood pressure (SBP) less than 90 mm Hg, cardiac index (CI) less than 2.2 L/min/m$^2$, and pulmonary capillary wedge pressure greater than 15 mm Hg, indicating inadequate cardiac function despite adequate preload.

## Pathophysiology

### MYOCARDIAL ISCHEMIA AND INFARCTION

With progressive atherosclerosis of the coronary arteries, normal intraluminal diameter is preserved initially through compensatory outward remodeling; however, eventually these stenoses become functionally important and coronary artery disease becomes symptomatic.[7] Plaque rupture may occur at any time, leading to intraluminal thrombosis.[8] Usually this occurs in angiographically insignificant arteries, but it may cause total occlusion of epicardial arteries, resulting in acute myocardial hypoperfusion and ischemia. Occlusion of coronary arteries for less than 15 min results in reversible myocardial injury; longer periods result in irreversible damage.[9,10] Brief periods of ischemia correspond clinically to periods of angina (stable or unstable) and may occur on a daily basis[11]; longer periods result in MI.

### STUNNED MYOCARDIUM

Within the first few minutes of ischemia, hypoxic myocytes stop contracting, resulting in regions of akinesia and dyskinesia.[11] After reperfusion (whether by relaxation of coronary artery spasm, cessation of exercise in stable angina, or pharmacologic or mechanical reperfusion), regions of viable post-ischemic myocardium may take hours to days to return to normal function; this delay has been termed myocardial stunning.[12–14] It originally was described in canine models of coronary occlusion and reperfusion and represents contractile dysfunction after *acute* ischemic injury. It includes left ventricular (LV) dysfunction after thrombolysis or angioplasty and may be involved in unusual cases of coronary spasm and severe exercise-induced ischemia. The pathogenesis of myocardial stunning is not completely understood. The primary mechanism is thought to be liberation of oxygen free radicals and myocyte adenosine triphosphate (ATP) depletion during reperfusion, but alterations in calcium homeostasis (including excitation-contraction decoupling resulting from sarcoplasmic reticulum dysfunction, calcium overload, and decreased responsiveness of myofilaments to calcium) may play a significant role.[11,15] Although investigators have suggested that calcium channel blockers or free radical scavengers may be useful in the treatment of myocardial stunning, inotropic support of the stunned myocardium until spontaneous recovery occurs remains the mainstay of treatment. Whatever the cause, stunned myocardium results in regions of reperfused, viable, but temporarily dysfunctional myocardium after an acute ischemic event. With sustained reperfusion, there is the potential for recovery of function.

### HIBERNATING MYOCARDIUM

Historically, it was thought that ventricular wall dysfunction in patients with coronary artery disease results from regions of infarcted myocardium. However, with the advent of reperfusion therapies, it came to be recognized that some dysfunctional myocardium can recover after the return of blood flow to ischemic regions.[16,17] It is believed that these regions of *chronically* ischemic myocardium go into a state of "hibernation" in which metabolic activity is downregulated. This represents an adaptive process that reduces oxygen consumption and prevents irreversible ischemic damage.[16–18] Identification of patients with hibernating myocardium is important, because regions of hibernating myocardium consist of viable cells and revascularization may reverse the dysfunction and ameliorate LV failure.

### CARDIOGENIC SHOCK

Acute MI leads to cardiogenic shock through ischemic dysfunction of myocytes and loss of effective contractility. The poor outcomes associated with this syndrome are due, at least in part, to the progressive nature of the dysfunction, in which worsening hypoperfusion leads to increasing ischemic and infarcted regions of myocardium. Cessation of

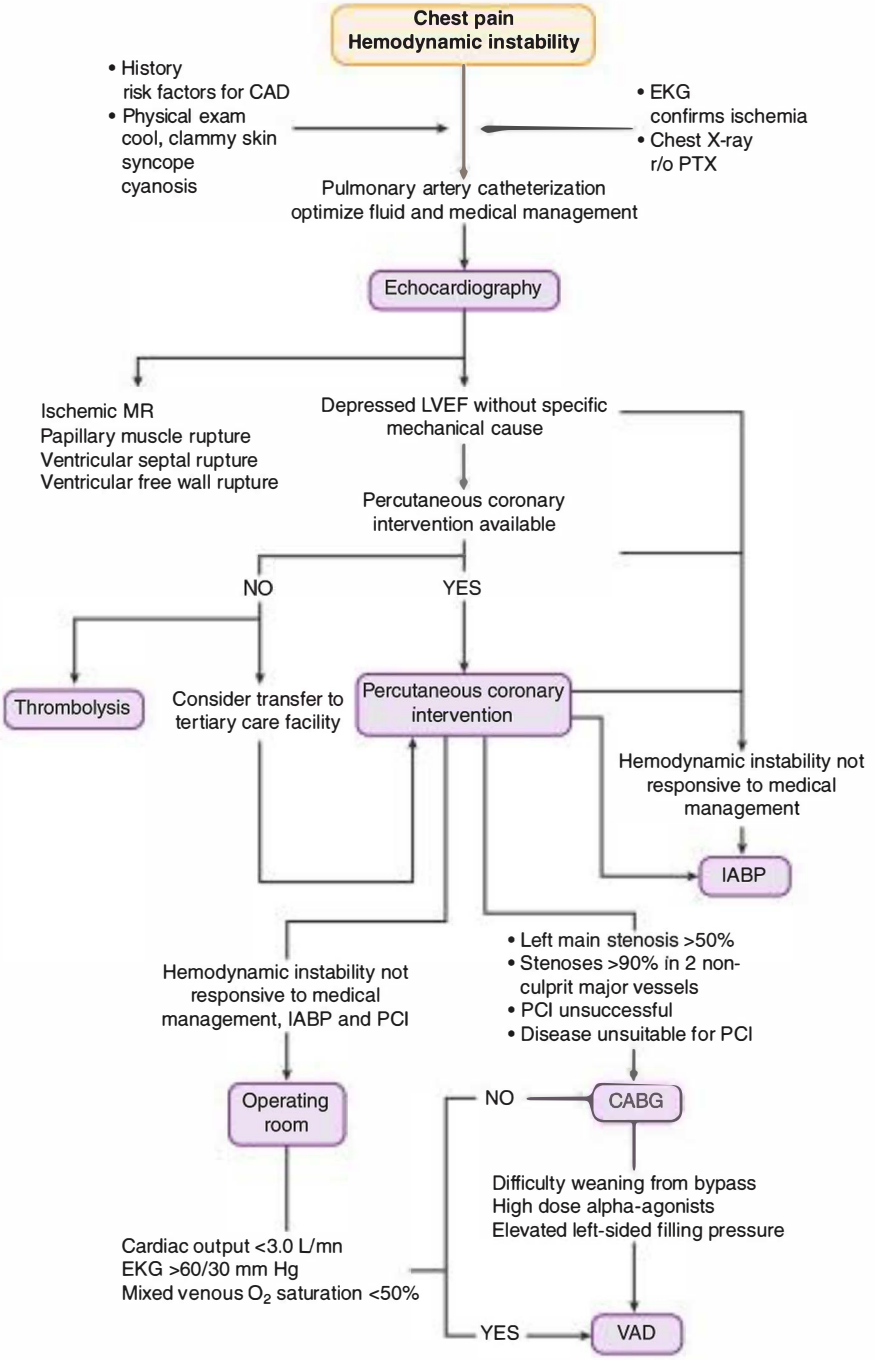

**FIGURE 31-1** Decision-making flowchart: Management of patients in cardiogenic shock. CAD, coronary artery disease; EKG, electrocardiogram; PTX, pneumothorax; PCI, percutaneous coronary intervention; IABP, intra-aortic baloon pump; CABG, coronary artery bypass grafting; VAD, ventricular assist device.

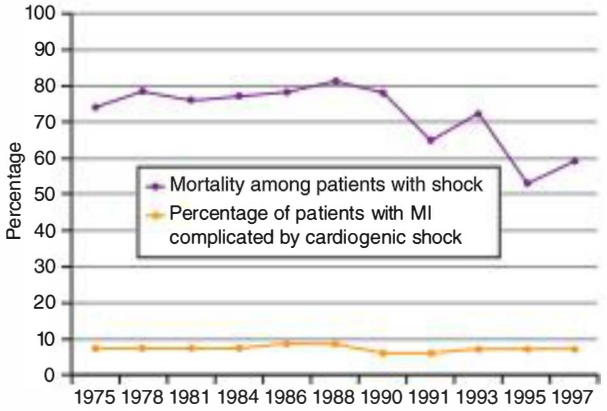

**FIGURE 31-2** Temporal trends in the incidence of cardiogenic shock after myocardial infarction and in mortality among those patients. (Data from Goldberg RJ, Samad NA, Yarzebski J, et al. Temporal trends in cardiogenic shock complicating acute myocardial infarction. *N Engl J Med* 1999;340(15):1162–1168.)

this "vicious cycle" must occur early to increase survival rates in patients who present in cardiogenic shock after MI (Fig. 31-2).

Cardiac function depends on a complex interplay of a variety of factors: myocyte contractility, preload, afterload, and electrical coordination. After myocardial damage, ischemic myocytes lose contractile function. This results in a decrease in stroke volume and cardiac output. To compensate for this loss, sympathetic tone is increased, and this results in tachycardia, systemic vasoconstriction, and increased contractile function in the remaining, nonischemic myocardium. Although these mechanisms help maintain both systemic and coronary perfusion, they also lead to increasing cardiac workload and oxygen consumption in the remaining myocytes.

If the remaining portions of the heart are able to maintain cardiac output and blood pressure, a compensated state may develop that allows for systemic and coronary perfusion without extension of the infarct. However, if the compensatory mechanisms cannot meet the increased demand, the area of ischemic and infarcted myocardium increases, leading to a downward spiral in cardiac function and ultimately to shock. Once mean arterial blood pressure falls below 70 mm Hg, coronary blood flow becomes severely restricted.[19] This spiral toward shock and ultimately death is supported by autopsy studies that have shown that infarcted regions of myocardium contain varying degrees of progression, suggesting an initial insult followed by multiple subsequent infarction events.[20] Traditionally, cardiogenic shock was thought to occur after the loss of approximately 40 percent of LV muscle mass.[21] Although studies have varied in the precise definition of hemodynamic variables, most would include SBP less than 90 mm Hg, cardiac index less than 2.2 L/min/m$^2$, and pulmonary capillary wedge pressure (PCWP) less than 15 mm Hg.[22,23]

### RIGHT VENTRICULAR DYSFUNCTION

Most patients with cardiogenic shock related to ventricular dysfunction have primarily LV failure; in the SHOCK (SHould we emergently revascularize Occluded Coronaries in cardiogenic shoCK) trial, nearly 80 percent of patients presented with shock resulting from predominant LV failure.[24] In contrast, less than 3 percent of patients presented with isolated right ventricular (RV) failure. However, despite younger age and a lower incidence of multivessel disease, a similar mortality rate was observed in the group with RV infarcts.[4] A variety of factors may contribute to this phenomenon, including RV dependence on atrial filling that may be compromised by atrioventricular (AV) dissynchrony, poor RV compensation for ischemia secondary to the large surface area and thin free wall, and concomitant LV dysfunction with loss of septal assistance to RV systole.

### PERIPHERAL EFFECTS

Traditionally, the vicious cycle of ventricular dysfunction was thought to be the primary pathophysiologic process involved in the development of ventricular dysfunction and cardiogenic shock. More recently, data have begun to suggest that the pathophysiology of cardiogenic shock may be more complicated.[25] Patients in the SHOCK trial and registry have been found to have a wide range of ejection fractions with a mean of approximately 30 percent, and systemic vascular resistance (SVR) was not universally elevated despite the use of vasopressors.[23,25–27] Based on studies of nitric oxide species, Hochman[25] concluded that some patients may have a significant component of systemic hypoperfusion related to a systemic inflammatory response caused by the release of inflammatory cytokines, and the SHOCK-2 (Should we inhibit nitric Oxide synthase in patients with Cardiogenic Shock) trial was designed to evaluate additional medical therapies directed toward the inhibition of inflammatory and vasodilatory mediators of shock.[25]

## Clinical Features

Precise estimates of the incidence of cardiogenic shock after acute MI are difficult to obtain because many patients die before reaching medical care. Furthermore, varying definitions of cardiogenic shock may contribute to variation among studies. The early report by Griffith and associates[28] had an incidence of nearly 20 percent; however, more recent studies have shown a consistent incidence of 6 to 10 percent.[2,29–31] The high incidence reported by Griffith may have been due in part to the inclusion of patients with underresuscitated hypovolemic shock in an era before invasive hemodynamic monitoring.[5] Despite advances in the diagnosis and treatment of patients with MI, the incidence of cardiogenic shock in this population over the past three decades has remained relatively constant.[2] Although mortality rates have improved (Fig. 31-2), patients diagnosed with cardiogenic shock during an admission for MI still have a substantially higher

in-hospital mortality rate than do those without shock (59 vs 8 percent).[2,23] Overall cardiogenic shock accounts for more than 55 percent of the in-hospital mortality of MI.[30] In addition, long-term survival of patients with cardiogenic shock remains significantly lower than that in patients without it even after hospital discharge.[32]

Interestingly, although patients may present to the hospital in cardiogenic shock, a significant proportion (anywhere from 44–90 percent) develop shock after admission.[30,33] In-hospital mortality is similar in both groups, although there may be a long-term survival advantage among patients who develop shock after hospital admission.[30,34,35] Median time to the development of shock has varied in reported series from 5 h to nearly 24 h.[24,30,33] This raises the question of whether initial therapies may contribute to the development of cardiogenic shock in some patients and, in light of the high mortality associated with the development of shock (independent of time to onset), suggests the importance of initiating early preventive measures.

The clinical presentation begins with the classic symptoms of MI. With the onset of cardiogenic shock, physical signs of hypoperfusion begin to predominate as oxygen delivery to vital organs becomes impaired: cold and clammy extremities, ashen or cyanotic skin, oliguria, and an altered sensorium.[1] Risk factors for the development of cardiogenic shock include age, diabetes, and a previous MI.[30,36] In addition, studies have demonstrated a correlation between large infarct size (as measured by peak cardiac enzyme levels), anterior MI, a depressed left ventricular ejection fraction (LVEF), and the development of shock.[36,37] Those who had undergone coronary artery bypass grafting (CABG) in the past, however, were less likely to develop shock during their admission.[30]

## Diagnostic Modalities

Assessment of a patient with systemic hypoperfusion should begin with the exclusion of noncardiac causes. Other causes of shock include hypovolemia, sepsis, pericardial tamponade, aortic rupture, tension pneumothorax, and anaphylaxis (Table 31-1). In light of the poor outcomes associated with the onset of cardiogenic shock after MI, initiation of therapies to improve systemic perfusion should not be delayed.

An electrocardiogram (ECG) should be performed immediately. Absence of electrocardiographic changes associated with ischemia essentially excludes the diagnosis of post-MI cardiogenic shock. A chest x-ray will rule out pneumothorax as a cause of circulatory collapse. History and physical examination also should assist in differentiating cardiogenic shock from other causes, such as sepsis, anaphylaxis, and neurogenic. In fact, despite the vast armamentarium of advanced diagnostic tests, physical findings remain significant predictors of in-hospital mortality. In the global utilization of streptokinase and tissue plasminogen activator

(tPA) for occluded arteries (GUSTO trials), subjective signs of hypoperfusion were among the most significant predictors of 30-day mortality: altered sensorium [odds ratio 1.68, 95 percent confidence interval (CI) 1.19–2.39], cold clammy skin (1.68, 95 percent CI 1.15–2.46), and decreased urine output (2.25, 95 percent CI 1.61–3.15).[35]

Initial laboratory investigations should focus on evaluating perfusion and oxygenation by measuring arterial blood gas as well as assessing levels of cardiac enzymes and electrolytes and measuring a hematocrit. Levels of cardiac enzymes and hematocrit in particular have prognostic significance in patients with acute MI.[38–42] Invasive monitoring of blood pressure should be initiated rapidly, as noninvasive cuff pressures may underestimate actual pressure significantly in the setting of peripheral vasoconstriction. In the absence of evidence of pulmonary edema (on physical examination or chest x-ray), volume status may be assessed by the patient's response to intravenous (IV) fluid resuscitation. Perhaps most important in the final determination of cardiac function and etiology are pulmonary artery catheterization and echocardiography.

### ECHOCARDIOGRAPHY

Rapid echocardiography (ECHO) is an important tool in the diagnosis and management of patients with cardiogenic shock. It allows for an expedited and accurate assessment of overall cardiac function. Multiple studies have shown that the ejection fraction is an important predictor of outcome even when it is measured within 24 h of presentation.[26,43] In addition, it can exclude other causes of circulatory collapse unrelated to ventricular dysfunction such as pericardial tamponade, IMR, and ventricular free wall or septal rupture, which may require different therapies.

### PULMONARY ARTERY CATHETERIZATION

Placement of a pulmonary artery catheter allows direct measurement of right-sided cardiac pressures and extrapolation to left-sided filling pressures. Patients in cardiogenic shock are expected to have poor cardiac function, with adequate ventricular preload leading to depressed cardiac output and hypotension (Table 31-2). In the setting of ventricular infarction, diastolic dysfunction may contribute to impaired ventricular filling, requiring an even higher PCWP to maintain cardiac output. Even in the absence of hypotension, some patients may have evidence of systemic hypoperfusion (and its accompanying clinical signs); their in-hospital mortality, although lower than that of patients with hypotension (43 vs 66 percent), is high. Although clinical characteristics are important, hemodynamic monitoring should be initiated rapidly to obtain measurements of ventricular preload and cardiac output.

Recently continuous, arterial pressure-based cardiac output measurement devices have been introduced. These devices provide real-time continuous hemodynamic monitoring using an arterial catheter. They can provide data to diagnose and guide treatment while avoiding the cost and complications of pulmonary artery catheters.[44]

## Medical Therapies

As was noted above, therapies should not be delayed while one awaits diagnostic test results. Initial management should be directed immediately toward improving systemic and coronary perfusion and oxygenation. Supplemental oxygen should be delivered, and mechanical ventilation should be initiated when appropriate. Electrical complications of acute MI are common and before the development

of coronary care units, they constituted the most common cause of death.[45] Depending on the location of the infarct, a variety of rhythm disturbances may occur, including tachy- and bradyarrythmias in both the atria and the ventricles. Therefore, telemetry monitoring should be initiated to screen for electrical dysfunction and allow for early treatment. Rapid correction of rhythm disturbances with antiarrythmic agents or cardioversion may be required, as AV dissynchrony may contribute to poor cardiac function. The use of analgesics (morphine sulfate or fentanyl) to control pain is also an important tool in reducing sympathetic tone and thus decreasing preload, afterload, and myocardial work.

## VOLUME RESUSCITATION AND ELECTROLYTE REPLACEMENT

Although cardiac dysfunction accounts for most of the decreased cardiac output and systemic hypoperfusion, relative hypovolemia may coexist in as many as 20 percent of patients with cardiogenic shock.[46] Hemodynamic parameters measured with a pulmonary artery catheter should guide resuscitation efforts. Optimal ventricular filling pressures may vary among patients. Initial infusion with either normal saline or Ringer's lactate is appropriate, although blood products should be used early. In patients over 65 years of age with a hematocrit below 33 percent, blood transfusion during admission with MI is associated with a decrease in 30-day mortality (conversely, patients with an admission hematocrit above 36 percent who received a transfusion had a higher mortality rate).[42] Among patients with a hematocrit below 27 percent who do not receive a transfusion, the mortality rate has been shown to be approximately 50 percent, three times higher than that of patients with a normal hematocrit (above 37 percent).[42] Recently it has been suggested that patients requiring transfusions were more ill at baseline and at increased risk of death.[47] Cardiac myocyte dysfunction is worsened by alterations in the electrolyte and acid–base environment. Maintenance of appropriate electrolyte levels is therefore essential, as is optimizing the patient's acid-base status.

## VASODILATORS

Pharmacologic therapies such as nitrates, angiotensin-converting enzyme (ACE) inhibitors, and β-blockers have proven effectiveness in reducing mortality in patients with MI. However, all these agents have the potential to cause systemic hypotension; their use should be limited in patients in cardiogenic shock. Nitroglycerin has been shown to improve myocardial oxygen delivery and reduce oxygen demand as well as augment the antiaggregatory effects of aspirin on platelets.[48–50] Nitroglycerin also has been shown to reduce ischemia and infarct size. Although it has been difficult to demonstrate a survival benefit among patients treated with nitrates in large trials such as the Grupo Italiano per lo Studio della Sopravivenza nell'infarto Miocardico (GISSI) 3 study,[51] as many as half the patients in the placebo group received off-label nitrates, probably diluting the detection of a real benefit. Also, seven smaller studies demonstrated an impressive reduction (41 percent) in post-MI mortality with the use of nitroglycerin.[52]

Although IV nitroprusside has many of the same pharmacologic effects as nitroglycerin, some differences make it less useful in patients with acute MI; most importantly, it may exacerbate coronary steal by failing to promote collateral blood flow to ischemic myocardium.[53] In light of the salutary effects of nitrates on cardiac work and the potential decrease in mortality, IV nitrate therapy (preferably with nitroglycerin) should be started when systemic arterial blood pressure allows. The initial doses should be low (5–10 mg/min) with rapid titration upward to optimize arterial blood pressure and LV filling pressures (PCWP between 15 and 22 for patients in severe cardiac failure).

## INOTROPIC SUPPORT

If optimization of ventricular filling pressures fails to ameliorate systemic hypoperfusion and hypotension, the use of inotropic support and intra-aortic balloon counter-pulsation (IABP) should be considered. A variety of inotropic agents are available, and the choice of a specific drug should be tailored to the specific clinical and hemodynamic status of the patient, particularly the degree of systemic hypotension.

***Dopamine.*** In patients with an SBP below 80, dopamine is one of the first-line cathecholamines because it has both inotropic and vasoconstrictive effects. Dopamine interacts with a variety of receptors in a dose-dependent manner. These receptors include the dopamine (DA)-1 receptors in the renal vasculature that mediate renal vasodilatation,[54] $\beta_1$-adrenergic receptors in the heart leading to increased inotropy and chronotropy, and α-adrenergic receptors in the peripheral vasculature leading to increased vascular resistance. As the dose increases, the predominant effect changes; however, there are no precise cutoffs, and the response to dopamine may vary between patients.[54]

At low doses (0.5–3.0 μg/kg/min) it acts primarily as a dopaminergic agonist, increasing renal blood flow. At higher doses (3–5 μg/kg/min) β-adrenergic effects become noticeable, although dopaminergic effects still dominate. At these doses, improvement in renal perfusion depends primarily on the increase in cardiac output rather than on dilatation of the renal arterial bed.[55,56] Between 5 and 10 μg/kg/min, β-adrenergic effects become dominant and α-adrenergic effects become noticeable. Finally, in the range of 10 to 20 μg/kg/min, dopamine functions primarily as an α-adrenergic agent, leading to significant peripheral vasoconstriction. At doses above 20 μg/kg/min, coronary vasoconstriction may predominate.[52]

Many of the presumed renal protective effects of low-dose dopamine have come under attack recently.[54,57] The renal vasodilatation thought to be related to dopaminergic stimulation actually may be due to augmentation of cardiac output through both increased stroke volume and increased heart

rate.[58] Thus, dopamine should be used with care in patients in cardiogenic shock, in whom the increased inotropy may increase myocardial oxygen demand beyond the increase in oxygen delivery, leading to further ischemia; this is particularly of concern at high doses, in which case coronary vasoconstriction may lead to infarction of at-risk myocardium. In fact, the recently published SOAP II study demonstrated that patients in shock treated with dobutamine were at increased risk of developing arrhythmias, and patients in cardiogenic shock treated with dobutamine had a significantly increased mortality at 28 days when compared with patients given norepinephrine.[59] However, dopamine remains an important agent in the initial management of hypotension unresponsive to fluid resuscitation, and the necessity for high-dose dopamine should lead to the insertion of an IABP to protect myocardium at risk for further ischemia and infarction.

***Dobutamine.*** In contrast to dopamine, dobutamine causes peripheral vasodilatation in association with its inotropic effects. Therefore, it is best used in patients with SBP greater than 80. Dobutamine originally was thought to be a selective $\beta_1$-adrenergic agonist, but it now is recognized that it also has $\alpha$- and $\beta_2$-adrenergic effects. As with dopamine, the relative importance of these effects changes with the dose.[5] At rates between 2.5 and 15 mg/kg/min, dobutamine increases cardiac output without significantly affecting peripheral vascular resistance (probably as a result of stimulation of both $\alpha_1$-mediated vasoconstriction and $\beta_2$-mediated vasodilatation).[60] At higher doses, $\alpha_1$-adrenergic effects may begin to predominate with an increase in heart rate, LV afterload, and myocardial oxygen demand. In contrast, at lower doses, myocardial oxygen demand may remain constant despite increased contractility because of the reduction in peripheral vascular resistance, ventricular volumes, and wall stress.[61]

***Isoproterenol.*** Isoproterenol is a $\beta$-adrenergic agonist used primarily in the treatment of postcardiotomy cardiogenic shock. It has both an inotropic and a chronotropic effect on the heart and results in systemic vasodilatation. The increase in cardiac output seen with isoproterenol infusion is due largely to a resultant increase in heart rate.[62] Because heart rate is a major determinant of myocardial oxygen demand, isoproterenol infusion may increase myocardial oxygen consumption.[63] In addition, it has been shown to shunt blood from ischemic myocardium to nonischemic areas.[64] This also results in an increase in ventricular instability that may result in ventricular arrhythmias even at relatively low doses.[63] In light of these problems, the use of isoproterenol in the setting of post-MI cardiogenic shock largely has been abandoned. It may have some application in a hypotensive patient with bradycardia, but transvenous pacing is preferred.

***Phosphodiesterase Inhibitors.*** Milrinone and amrinone are nonadrenergic inotropic agents. In addition, they have peripheral and pulmonary vasodilatory effects. Although they have minimal chronotropic and arrhythmogenic actions compared with the cathecholamines,[64] they also have long half-lives. This mitigates their usefulness in the acute post-MI setting. Therefore, they are used only when other agents have proved ineffective.[65,66] Most commonly, this occurs in the setting of right-sided heart failure, in which the increased pulmonary vasodilation of these agents has added benefit.

## VASOPRESSORS

In patients without adequate arterial blood pressure, vasopressor agents may be required to maintain systemic perfusion.

***Norepinephrine.*** Norepinephrine is a combined $\alpha$- and $\beta$-adrenergic agonist. At low doses, its effects include primarily increased cardiac output and arterial blood pressure (mainly $\beta$-adrenergic-mediated).[67] At higher doses, vascular resistance is markedly increased and cardiac output actually may fall. Treatment with norepinephrine in patients with cardiogenic shock results in rapid increases in blood pressure, vascular resistance, and the LV stroke work index.[63] The last effect presents the main downside to norepinephrine in the setting of post-MI shock. Although the increased blood pressure improves myocardial oxygen supply through increased coronary blood flow,[68] the increase in the stroke work index increases oxygen demand in a potentially ischemic heart. While a shift from anaerobic to aerobic metabolism was observed with norepinephrine infusion in patients with cardiogenic shock, myocardial oxygen extraction remained abnormally high.[68] Other side effects of norepinephrine infusion include aggravation of oliguria through constriction of the renal arterial supply, increased risk of ventricular arrhythmias, and peripheral ischemia and limb loss. Despite these drawbacks, norepinephrine is a potent vasopressor with a rapid onset; its use is appropriate in severely hypotensive patients to maintain mean arterial pressure in the range of 70 to 80 mm Hg while other therapies are instituted.

***Vasopressin.*** Arginine vasopressin has been used frequently in patients with vasodilatory shock. In a variety of circumstances that include septic shock and postcardiotomy vasodilatory shock, an endogenous vasopressin deficiency exists.[69,70] Although that deficiency has not been seen in small series of patients in cardiogenic shock,[69] the recent recognition of a possible vasodilatory component in some patients in the SHOCK trial[25] may indicate a role for vasopressin in this setting. Traditionally, vasopressin was thought to have a negative impact on coronary perfusion; however, this was based on experimental data in normotensive dogs. Data in hypotensive models suggest that vasopressin increases coronary perfusion.[71,72] In addition, clinical trials in critically ill patients with vasodilatory shock suggest that the use of a vasopressin infusion results in decreased norepinephrine requirements, an improved cardiac index, a decreased stroke work index, and better preservation of gastric perfusion.[73] Although further study is necessary, vasopressin may provide a useful adjunct to norephinephrine in the maintenance of systemic blood pressure during the

initial phase of cardiogenic shock before the institution of more definitive therapies.

None of the pharmacologic agents listed above has been shown to have a survival benefit in the treatment of cardiogenic shock. They all have significant side effects, and any attempt to increase cardiac output or systemic blood pressure in an attempt to increase coronary perfusion carries a risk of increasing myocardial ischemia. The use of vasopressors should be limited to keep mean arterial pressure at 70 to 80 mm Hg, not to return patients to a normotensive state, and inotropes should be used sparingly and under careful monitoring of hemodynamic parameters. In all cases, the most appropriate uses of these agents are as temporizing measures until the initiation of IABP placement, mechanical circulatory support, and revascularization.

## THROMBOLYSIS

The improvement in outcome with thrombolysis in patients with acute MI has been well established,[74–76] but in patients with cardiogenic shock, the benefits of this therapy are less clear. Many studies explicitly excluded patients with cardiogenic shock, and even more failed to describe the inclusion or exclusion of those patients.[74,77,78] Thrombolytics may decrease the incidence of the subsequent development of cardiogenic shock,[75,76,79] but no trial has demonstrated a convincing reduction in mortality in patients with already established cardiogenic shock.

Mathey and associates reported the survival of three patients with cardiogenic shock treated with streptokinase in 1980.[80,81] In a larger series of 44 patients, however, mortality remained at 66 percent.[82] The GISSI-1 trial randomized a total of 280 patients with cardiogenic shock. Overall mortality in that group was 70 percent and did not differ between those treated with streptokinase (69.9 percent) and controls receiving placebo (70.1 percent).[75] Mortality rates were similar in trials comparing various thrombolytic regimens: The International Study Group reported mortality rates of 78.1 and 64.9 percent among 246 patients with cardiogenic shock treated with tPA or streptokinase[83]; the GUSTO trial also had a high 30-day mortality among 2972 patients treated with streptokinase (51 percent) or tPA (57 percent).[30]

Interestingly, among the 44 patients in the Society for Cardiac Angiography registry, arterial patency was achieved in only 19 patients (44 vs 71 percent in the registry as a whole), among whom mortality dropped to 42 percent (vs 84 percent in patients without reperfusion, $p = 0.0005$). In the GUSTO trial, lytic therapy was less likely to be successful in patients with cardiogenic shock [Thrombolysis in Myocardial Infarction (TIMI) 0 or 1 flow 42.9 vs 27.7 percent, $p < 0.001$].[34] However, with successful reperfusion, mortality can be decreased significantly.[34,82,84] Thus, the poor performance of thrombolysis in the setting of cardiogenic shock may be secondary to an inability to achieve patency.

The decreased ability of thrombolysis to achieve successful reperfusion in the setting of cardiogenic shock is not completely understood and probably involves a combination of hemodynamic, metabolic, and mechanical factors.[85] Hypotension and coronary hypoperfusion probably play a significant role. In the setting of cardiogenic shock, research in canine models has suggested that the rate and degree of thrombolysis after intracoronary injection of tPA are depressed compared with those in normotensive controls,[86,87] and in clinical trials, hypotension was associated with lower TIMI flow grades after thrombolysis.[88] The augmentation of blood pressure through vasopressors or an IABP may improve the success rate of thrombolysis in patients with cardiogenic shock.[87,89,90]

Despite these limitations, thrombolysis remains an important treatment for acute ST-elevation MI when percutaneous catheter-based interventions are not available. Indications and contraindications for thrombolytic therapy are well established (Table 31-3).[91] However, recent data suggest that even when percutaneous catheter-based interventions are unavailable, transport to a facility with those services improves survival and decreases complications.[92] Furthermore, the use of IABPs (see below) to stabilize patients for transport to a tertiary care facility has been shown to be a safe alternative to treatment with thrombolytics.[66] Although thrombolysis is an option in limited circumstances, mechanical revascularization delivers the best outcomes in acute MI patients.

## INTRA-AORTIC BALLOON COUNTERPULSATION

In 1958, Harken described a mechanism for diastolic augmentation of blood flow.[93,94] However, initial attempts to use femoral–femoral bypass to augment diastolic flow met with technical difficulties, including the need for bilateral femoral arteriotomies and problems with the extracorporeal pump. Efforts at demonstrating increased cardiac perfusion failed. However, after work by Moulopoulos and associates[95,96] in 1968, Kantrowitz and coworkers described the first use of an IABP to provide diastolic flow augmentation in patients with cardiogenic shock.[97] Initial models required operative placement via a femoral arteriotomy, but in 1979 Bregman and Casarella introduced a percutaneously placed model inserted through a 12F sheath.[98] Further refinements have included a dual-lumen design, wire-guided placement, reduced sheath sizes (8F or 9F for 30–50-mL balloons), and the use of helium to inflate and deflate the balloon rapidly.[99,100]

Most commonly, the IABP is inserted percutaneously into the femoral artery, using a modified Seldinger technique. After puncture of the artery, a J-wire is advanced into the aorta. The needle is removed, and the IABP catheter is inserted over the wire into the descending aorta. When properly placed, the balloon should lie immediately distal to the origin of the left subclavian artery (Fig. 31-3). In specialized cases such as pediatric patients and those with significant peripheral vascular disease that precludes the use of the femoral artery, other insertion sites may be used, including the ascending aorta, aortic arch, and subclavian, axillary, and iliac arteries.[101–107]

## TABLE 31-3: Indications and Contraindications for Thrombolysis

***Indications***

Clinical history and presentation strongly suggestive of myocardial infarction within 6 h plus one or more of the following:
1 mm ST elevation in two or more contiguous limb leads
2 mm ST elevation in two or more contiguous chest leads
New left bundle branch block
2 mm ST depression in $V_{1-4}$ suggestive of true posterior myocardial infarction
Patients presenting with above within 7–12 h of onset with persistent chest pain and ST-segment elevation
Patients age <75 years presenting within 6 h of anterior wall myocardial infarction should be considered for recombinant tissue plasminogen activator

***Contraindications***

Absolute
Aortic dissection
Previous cerebral hemorrhage
Known history of cerebral aneurysm or arteriovenous malformation
Known intracranial neoplasm
Recent (within 6 months) thromboembolic stroke
Active internal bleeding (excluding menstruation)
Patients previously treated with streptokinase or an isolated plasminogen streptokinase activator complex (APSAC or anistreplasse) shoud receive tissue plasminogen activator, reteplase, or tenecteplase
Relative
Severe uncontrolled hypertension (blood pressure >180/110 mm Hg) on presentation or chronic severe hypertension
Current use of anticoagulants or known bleeding diathesis
Recent (within last 2–4 weeks) trauma, including head injury or traumatic or prolonged (>10 min) cardiopulmonary resuscitation
Recent (within 3 weeks) major surgery, organ biopsy, or puncture of noncompressible vessel
Recent (within last 6 months) gastrointestinal or genitourinary or other internal bleeding
Pregnancy
Active peptic ulcer disease

Adapted from Lip GY, Chin BS, Prasad N. ABC of antithrombotic therapy: Antithrombotic therapy in myocardial infarction and stable angina. *BMJ* 2002;325(7375): 1287–1289.

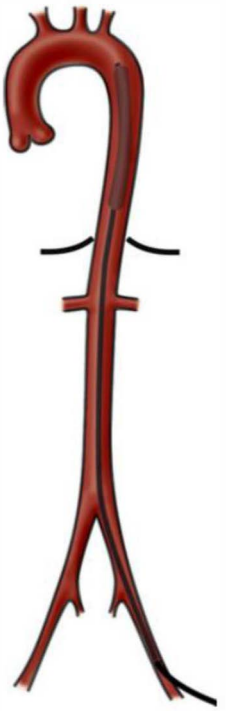

**FIGURE 31-3** Schematic diagram of intra-aortic balloon pump placement. The balloon tip should be placed distal to the take-off of the left subclavian artery.

After insertion, the balloon is connected to a pump console that controls its inflation and deflation. The timing of these events is synchronized to the patient's cardiac cycle through the use of either electrocardiographic or aortic pressure-sensitive timing. The balloon inflates with the onset of diastole, displacing blood both proximally and distally and increasing intra-aortic pressure (diastolic augmentation). Immediately before systole, the balloon deflates, reducing obstruction to LV ejection (decreased afterload). With electrocardiographic timing, balloon inflation occurs (Fig. 31-4).

The decreased afterload results in a reduction in end-diastolic LV diameter and volume and a reduction in ventricular wall stress; a slight decrease in heart rate also is seen.[108] Multiple studies have shown that, as expected, the reductions in wall stress and heart rate, lead to a decrease in myocardial oxygen demand and consumption.[109] Through diastolic augmentation, the IABP increases coronary perfusion and myocardial oxygen delivery.[110] This increase in coronary blood flow has been observed in both hypotensive animals and patients with cardiogenic shock (Fig. 31-4).[109,111] Overall, these effects lead to improved hemodynamics (increased cardiac output, decreased PCWP, improved arterial blood pressure, and improved urine output)[112–114] along with improvement in myocardial metabolism (as reflected in decreasing oxygen extraction and a shift toward aerobic metabolism).[68]

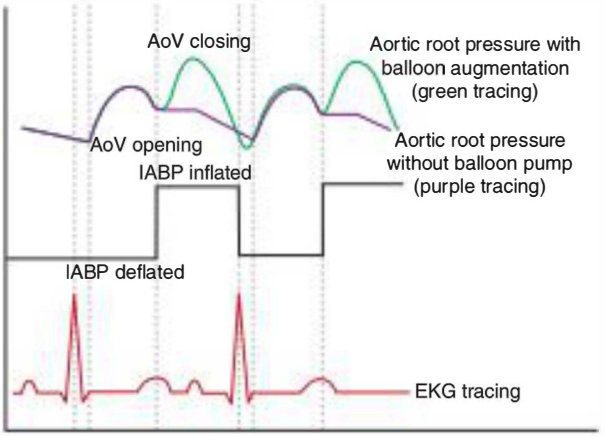

**FIGURE 31-4** Timing of balloon pump inflation and deflation. Deflation is timed to occur just before the QRS complex to reduce afterload maximally as the aortic valve opens. Inflation occurs at the dicrotic notch (corresponding to the peak of the T wave on the ECG). Augmentation of diastolic aortic pressure with balloon inflation is shown by the dark red tracing. IABP, intra-aortic balloon pump; EKG, electrocardiogram.

Despite these improvements in hemodynamic performance and myocardial metabolism, initial results with the IABP alone in the treatment of cardiogenic shock failed to demonstrate improvement in survival.[115,116,117] In a small randomized trial (30 patients) that compared optimal medical therapy for cardiogenic shock with IABP, in-hospital mortality was similar in both groups (50 percent with IABP vs 44 percent with medical management).[115] However, when IABP is combined with revascularization (via thrombolysis, angioplasty, or surgery), it appears that IABP improves both short- and long-term survival, though patient selection remains a confounding factor in these trials. As was noted above, in the setting of cardiogenic shock or hypotension, the rate and degree of thrombolysis are depressed.[87] Additional work with canine models demonstrated improvement in the rate and degree of thrombolysis as well as the time to reperfusion when IABP was added to thrombolytic therapy.[89,90] Observational studies in humans confirmed an advantage for IABP when it was used with thrombolytics.[118,119]

The GUSTO-1 trial was a large randomized trial that investigated the benefits of thrombolysis. In this trial, analysis of patients with cardiogenic shock who had an IABP placed on hospital day 0 or 1 showed a trend toward improved short-term survival (30-day mortality 48 vs 59 percent) when IABP was used and a significant reduction in 1-year mortality (57 vs 67 percent, $p = 0.04$).[120] The trend toward improved 30-day mortality with IABP remained when only patients undergoing revascularization were analyzed (47 vs 64 percent).[120] However, the 310 patients included were not randomized to IABP therapy, and the IABP group had significantly higher use of inotropes, pacemakers, pulmonary artery catheters, diagnostic angiography, and revascularization (both percutaneous and surgical). Most of the difference in survival occurred in the first days; this might have been due to earlier use of IABP but also might have resulted from selection of patients with a better prognosis for more aggressive interventions (including IABP and revascularization).

The larger SHOCK registry included nearly 900 patients who were collected prospectively but not randomized. Analysis of this group showed that patients with IABP use had lower in-hospital mortality than did those without it whether thrombolysis was used (47 vs 63 percent) or not (52 vs 77 percent).[121] Unfortunately, these data also were subject to significant selection bias, and the groups that had the best outcomes included those individulas who underwent revascularization regardless of the adjunctive treatment (thrombolysis with or without IABP support) they received. These results were supported by an analysis of the 23,180 patients with cardiogenic shock enrolled in the National Registry of Myocardial Infarction-2. In this group, use of IABP improved 30-day survival in patients receiving thrombolytics (adjusted odds ratio 0.82; 95 percent CI 0.72–0.93), but a slight increase in mortality was noted in patients undergoing percutaneous coronary angioplasty (PTCA) who had placement of an IABP.

These data suggest that the improvement in thrombolysis noted in the canine models when IABP was used for patients in cardiogenic shock may result in a real improvement in outcomes in those patients.[89,90] For patients not receiving thrombolysis, significant patient selection bias exists in all these studies; however, it is clear that IABP alone does not improve survival over medical therapy. Its use, as with inotropic support, should be as an adjunct to maintain systemic and coronary perfusion and minimize infarct expansion before revascularization. Thus, in hospitals without cardiac catheterization capability, stabilization with IABP and transfer to a tertiary care facility may be the best option.[66] Although selection bias is again a confounding factor, retrospective analysis has suggested improvement in community hospital survival (93 vs 37 percent, $p = 0.0002$), transfer to a tertiary care center (85 vs 37 percent), and 1-year survival (67 vs 32 percent, $p = 0.019$) with the use of IABP in this setting.[122] A recent retrospective study suggests that placement of an IABP prior to PCI results in decreased in-hospital mortality and incidence of major adverse cardiac events when compared to patients having IABP placed after PCI (19 vs 59 percent and 23 vs 77 percent, $p = 0.007$ and 0.0004, respectively).[123] After revascularization, prophylactic use of IABP for 48 h has been shown to maintain patency of revascularized arteries.[124] Weaning of the IABP should be performed before weaning from inotropic and pressor support except when limb ischemia intervenes.

## Surgical Therapies

Multiple studies have shown that the patency of an infarct-related artery is an important predictor of LV function and mortality after acute MI.[125–131] In addition, most studies have

demonstrated worse outcomes with increasing time between symptom onset and reperfusion.[74,75,125,132] These findings were extrapolated to patients with cardiogenic shock, supporting an aggressive approach to early *mechanical* reperfusion for patients in shock after MI. Recently, prospective, randomized data in patients with post-MI cardiogenic shock have become available to define further the indications for and outcomes with emergent revascularization.

## ANGIOPLASTY

The SHOCK trial enrolled 302 patients with post-MI cardiogenic shock resulting from LV dysfunction and randomized them to receive either optimal medical management (including IABP and thrombolysis) or emergent mechanical revascularization [either percutaneous coronary intervention (PCI)(PTCA with or without stenting) or coronary artery bypass surgery]. Revascularization in this group occurred on average within 1 h of randomization for patients undergoing PTCA and within 3 h for those undergoing CABG. There was a trend toward improved 30-day mortality in the revascularization group (46.7 vs 56.0 percent, $p = 0.11$) and a significant reduction in 6-month mortality (50.3 vs 63.1 percent, $p = 0.027$) and 1-year mortality (53 vs 66 percent, $p = 0.025$).[23,43,133] Patients who had successful angioplasty (TIMI grade 2 or 3[134]) had very low mortality rates at 30 days (38 vs 79 percent, $p = 0.003$), and no patient who had a post-PCI occluded infarct artery survived (Fig. 31-5).[23,135] The only group that did not appear to benefit from a strategy of emergent revascularization were those over age 75 (30-day mortality 75.0 vs 53.1 percent, $p = 0.01$), although these results may have been affected by patient selection and a 25-percent revascularization rate before discharge among medically treated patients[23] and have been called into question by results from other studies.[136] The survival advantage seen in the early revascularization group remained at 3 and 6 years.[137] The importance of reducing time to reperfusion in patients with cardiogenic shock after MI has been reinforced by other nonrandomized studies.[138,139] In fact, the goal time period from presentation to the hospital to angioplasty balloon inflation (door-to-balloon time) is 90 min.[140] Significant predictors of poor outcomes in all patients include severity of MR,[26] initial TIMI flow, and culprit vessels other than the right coronary artery.[43]

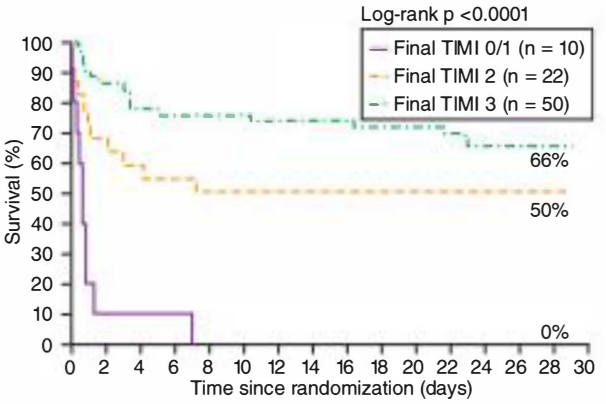

**FIGURE 31-5** Mortality after emergent percutaneous coronary intervention for postinfarction cardiogenic shock stratified by Thrombolysis in Myocardial Infarction (TIMI) flow grade. TIMI, thrombolysis in myocardial infarction. (From Webb JG, Lowe AM, Sanborn TA, et al. Percutaneous coronary intervention for cardiogenic shock in the SHOCK trial. *J Am Coll Cardiol* 2003;42(8):1380–1386.)

## STENTING

Percutaneous coronary stenting has been shown to improve outcomes and reduce angiographic restenosis during elective PTCA.[141–144] Although there was initial reluctance to use stents in the setting of a potentially unstable coronary thrombus, randomized studies have demonstrated that stenting in the setting of acute MI can be performed safely.[145] Unfortunately, the largest studies have failed to demonstrate a survival benefit from the use of stenting in the setting of MI and instead have shown a trend toward increased mortality with the use of primary stenting (although some have shown reductions in combined endpoints such as recurrent ischemia, infarction, and angina).[144,146,147] However, none of these studies included patients with post-MI cardiogenic shock.

Among patients with cardiogenic shock, Antoniucci and associates described a short- and long-term survival advantage to stent placement over angioplasty alone; however, again, selection bias may have played a role in those patients.[148] Similar results to those for MI alone have been obtained in other nonrandomized trials.[149] The Global Registry of Acute Coronary events has provided observational data that suggest an improvement in outcomes (PCI with stenting predicted hospital survival: odds ratio 3.99, 95 percent CI 2.41–6.62).[150] Thus, some evidence exists to support the use of stents in patients with cardiogenic shock; even without strong prospective evidence, it has become common practice (as many as 85 percent of the patients enrolled in the SHOCK trial between 1997 and 1998[135]). A prospective observational study utilizing the National Registry of Myocardial Infarction examined almost 300,000 patients presenting with ST elevation MI and cardiogenic shock. It was seen that patients undergoing primary PCI had decreased odds of death during the index hospitalization (odds ratio, 0.46; 95 percent CI, 0.40–0.53).[151] Further prospective, randomized investigations are needed to define the indications for stent placement in patients with MI and cardiogenic shock.

***Antiplatelet Agents.*** Among patients who have stents placed after MI, antiplatelet agents have become standard practice, as they appear to reduce short-term restenosis and the need for repeat revascularization.[152–155] In nonrandomized trials, combination treatment with abciximab (a glycoprotein IIb/IIIa inhibitor) decreased 1-month overall mortality (18 vs 42 percent, $p = 0.020$) and improved TIMI flow in the infarcted artery compared with stenting

alone.[156,157] However, these mortality rates are low, suggesting that the population studied may have been selected for more aggressive treatment. Additional large randomized trials are needed to assess the impact of adding antiplatelet agents to percutaneous stenting of stenosed arteries in patients with acute MI with cardiogenic shock. Currently all patients receiving drug eluting stents (DES) are placed on antiplatelet therapy for at least 1 year, as they are at increased risk for late in-stent thrombosis, a catastrophic complication.[158–161]

## CORONARY ARTERY BYPASS

Early outcomes with CABG in the setting of acute MI were poor,[162,163] but surgical revascularization within 6 h has shown to improve survival compared with medically treated patients.[164–169] These reports, however, were published as medical management was changing: Randomized trials were evaluating the efficacy of thrombolysis and PCIs in post-MI patients.[75,76,170] Unfortunately, CABG was not included in these studies. Furthermore, subsequent improvements in both interventional and surgical techniques may make comparisons to contemporary populations and treatments meaningless. Thus, the appropriate use of CABG in the setting of MI in general and cardiogenic shock in particular remains a matter of debate.

The results of the SHOCK trial demonstrated that early revascularization improved survival, and despite more severe disease, mortality in the group receiving CABG (guidelines for the use of emergent CABG included left main stenosis equal to or greater than 50 percent, stenoses greater than 90 percent in two nonculprit major vessels, and patients in whom PCI was unsuccessful or who had disease unsuitable for PCI) was similar to that in patients undergoing percutaneous interventions.[23] Large observational studies support the selective use of CABG in patients with cardiogenic shock; although patients in Killip class IV have seven times the CABG-associated mortality of those in Killip class I, mortality in this group is 27 percent, substantially lower than that in patients who do not receive revascularization and comparable to survival in patients undergoing PCI.[171] Although surgery within 3 days of transmural and 6 h of nontransmural MI has been associated with a higher mortality rate (Table 31-4),[172,173] Lee and associates documented decreased early mortality rates when operation occurs before 18 h in patients with cardiogenic shock (7 vs 31 percent).[174] Thus, in patients with ongoing ischemia or cardiogenic shock that is not amenable to medical stabilization, early revacularization with CABG is indicated; however, when possible, surgery should be delayed, especially in patients with transmural infarction.

Unfortunately, randomized data are not available, and the optimal indications for CABG in the setting of MI and cardiogenic shock remain ill-defined. In light of the excellent results obtained with thrombolysis and percutaneous revascularization, CABG probably will not become a primary therapy after MI whether or not cardiogenic shock intervenes; instead, it is best reserved for specific indications for which percutaneous revascularization is unsuccessful or inappropriate. One such indication for CABG surgery may be cardiogenic shock in the setting of left main coronary artery infarction. A recent study demonstrated that patients undergoing CABG in this situation had better survival at 30 days than those having PCI, 40 percent in the surgical group ($n = 6$) and 16 percent in the PCI group ($n = 15$; $p = 0.03$).[175] In addition, current American College of Cardiology/American Heart Association Guidelines Committee recommendations for initial reperfusion therapy in patients with three-vessel coronary disease in cardiogenic shock from AMI is CABG.[176]

**TABLE 31-4: Comparison of Hospital Mortality with Respect to Time of Operation**

| | *Mortality* | |
|---|---|---|
| **Time between CABG and MI** | **Transmural MI (%)** | **Nontransmural MI (%)** |
| <6 h | 12.1 | 11.5 |
| 6–23 h | 13.6 | 6.2[a] |
| 1–7 days | 4.3 | 3.5 |
| 8–14 days | 2.4 | 2.7 |
| ≥15 days | 2.6 | 2.7 |

CABG, coronary artery bypass grafting; MI, myocardial infarction.

Adapted from Lee DC, Oz MC, Weinberg AD, et al. Optimal timing of revascularization: Transmural vs nontransmural acute myocardial infarction. *Ann Thorac Surg* 2001;71(4):1197–1202; discussion 202–204.

***Perioperative Considerations.*** When emergent revascularization by CABG is indicated, timing is important and rapid transport to the operating room is critical; however, some techniques are available to assist in maintaining coronary and systemic perfusion during transport. As was noted above, the use of IABP is preferable to the use of inotropes and vasopressors because of the improvement in myocardial oxygenation and workload. In patients with circulatory collapse, percutaneous cardiopulmonary bypass (CPB) may be initiated via the femoral artery and vein. Flow rates of 3.5 to 5.0 L have been obtained with this method.[177]

Once the patient is in the operating room, anesthetic induction may lead to catastrophic hypotensive circulatory collapse. It is important that both surgery and perfusion teams be prepared for decompensation before the onset of anesthesia. Although the specific type of anesthetic agent used does not appear to alter myocardial oxygen utilization efficiency significantly,[178] a rapid narcotics-based regimen has been recommended.[179] Rapid institution of CPB to provide perfusion to threatened myocardium is essential.

Patients undergoing emergent CABG have high mortality rates; bleeding may contribute to that rate by decreasing

myocardial oxygen delivery. In addition, release of cytokines in response to large-volume transfusions as well as thromboxane $A_2$ release during CPB may worsen coagulopathy, pulmonary hypertension, and myocardial microvascular contraction responses worsening ventricular ischemia.[183]

The choice of a conduit should not be altered from that for elective cases. Although most surgeons use saphenous vein grafts (SVGs) to minimize bypass time, internal mammary artery (IMA) grafting has not been associated with increased complications compared with saphenous vein grafting even in the setting of cardiogenic shock, and late results with IMA grafts are significantly better than those with SVG.[184-186] To reduce MI, harvesting of the IMA can be performed after the initiation of CPB, cross-clamping, and cardioplegia.

In all cases, both antegrade and retrograde cardioplegia should be used for myocardial protection to ensure the delivery of cardioplegia to ischemic areas. Both antegrade and retrograde catheters can be placed before placement of the aortic cross-clamp to ensure rapid delivery of cardioplegia to the entire myocardium. The placement of a "bail-out" catheter across stenotic regions during PCI may assist in the delivery of cardioplegia to ischemic regions.[177] Various authors have advocated a variety of techniques for myocardial protection, including hypothermic fibrillatory arrest,[187,188] oxygenated crystalloid cardioplegia,[187,189] blood cardioplegia,[190,191] and substrate-enriched blood cardioplegia.[187,190] However, in a series of experimental studies, Buckberg and coauthors developed specific modifications of the reperfusion process that reduce myocardial oxygen demand and reperfusion injury in ischemic myocardium. These experimental studies subsequently were validated clinically.[191] Conditions favoring recovery of ischemic myocardium include the following: Decompression of the heart, which reduces myocardial oxygen demand by approximately 50 percent[192]; cardioplegic arrest reduces oxygen demand by approximately 90 percent compared with a beating heart[193]; myocardial metabolism is enhanced by warm blood cardioplegia that maintains normal energy production while decreasing energy demands[194]; low perfusion pressure reduces postischemic edema[195]; and prolonged reperfusion with cardioplegic arrest permits resuscitation of energy-depleted myocardium.[196] Therefore, the standard Buckberg protocol should be used to maximize myocardial protection in patients undergoing CABG who are in cardiogenic shock. This includes induction of cardioplegia with substrate-enriched warm blood cardioplegia for 3 to 5 min, followed by cold blood cardioplegia for 2 to 3 min and then by periodic small-volume infusions. In addition, an infusion of warm blood cardioplegia before removal of the cross-clamp ("hot shot") may improve myocardial recovery.[197]

The occluded artery supplying the largest region of ischemic but viable myocardium should be reperfused first. When vein grafts are used, after completion of the distal anastomosis, regional blood cardioplegia can be delivered to the ischemic area through a side branch of the graft while the proximal anastomosis is completed.

## VENTRICULAR ASSIST DEVICES AND HEART TRANSPLANTATION

In patients with cardiogenic shock refractory to maximal medical management and unimproved by percutaneous intervention or an IABP, implantation of a ventricular assist device (VAD) is a potentially lifesaving maneuver. Two classes of patients may benefit from the use of a VAD: (1) patients with stunned myocardium as a bridge to recovery and (2) patients with extensive infarction requiring a bridge to heart transplantation. Outside clinical trials, VADs are approved for use in patients pending transplantation; therefore, all patients should fulfill the general criteria for transplant recipient selection (Table 31-5).[198] Although complete evaluation is usually impossible in the acute setting, patients with obvious contraindications to transplantation (irreversible neurologic defects, coexisting active neoplasm, etc.) should not be considered for VAD implantation.

When used as a bridge to recovery for myocardial stunning, VAD implantation should be accompanied or preceded by mechanical revascularization, whether percutaneous or surgical. In this setting, the use of short-term VAD is appropriate. VADs suitable for short-term implantation include the Bio-medicus centrifugal pump and the Abiomed and Thoratec pumps. Although the centrifugal pump is easy to insert, it has a significant incidence of thromboembolic complications despite systemic heparinization, and its use largely has been supplanted by use of the pump devices.[199] The Abiomed VAD (AB5000) is a system recently approved by the Food and Drug Administration that consists of a fully automatic, vacuum-assisted console and a paracorporeal, pneumatically driven blood pump. The VAD is designed for short or intermediate termuse. The Thoratec pneumatically driven extracorporeal pump is also suitable for left, right, or biventricular short-term support and has the advantage of allowing significant patient mobility. Both devices require systemic anticoagulation. Percutaneous devices, such as the Abiomed Impella and the Cardiac Assist TandemHeart Pump, are being placed as a bridge to long-term VAD placement and bridge to recovery.[200,201]

In patients with large infarcts without the potential for myocardial recovery, the insertion of a longer-term VAD is required as a bridge to transplantation. Historically, the two most commonly used pulsatile devices were the Heartmate XVE and Novacor pumps. Both are wearable, pulsatile intracorporeal VADs with only a driveline traversing the skin. The Heartmate has the advantage of requiring only aspirin for antiplatelet activity, not systemic anticoagulation; this is achieved through the use of textured blood contact surface that forms a stable biological lining that is resistant to thrombus formation.[202] The Novacor device was discontinued by its manufacturer, World Heart in 2008. It was the first mechanical circulatory support device to support a single patient for more than 6 years.

Other devices with different pump mechanisms have been developed (Table 31-6). The Heartmate II, a continuous-flow VAD, was approved for bridge to transplantation use in 2007. Direct comparison of the Heartmate XVE and II

## TABLE 31-5: Indications and Contraindications for Heart Transplantation in the Acute Setting

***Indications***

Indications for cardiac transplantation determined by severity of heart failure despite optimal therapy

Definite indications
- $Vo_2$ max <10 mL/kg/min
- NYHA class IV
- History of recurrent hospitalization for congestive heart failure
- Refractory ischemia with inoperable coronary artery disease and left ventricular ejection fraction <20%
- Recurrent symptomatic ventricular arrhythmias

Probable indications
- $Vo_2$ max <14 mL/kg/min (or higher with multiple other risk factors)
- NYHA class III–IV
- Recent hospitalizations for congestive heart failure
- Unstable angina not amenable to coronary artery bypass grafting or percutaneous transluminal coronary angioplasty with left ventricular ejection fraction <0.25%

***Contraindications***

General contraindications
- Presence of any noncardiac condition that would shorten life expectancy or increase the risk of death from rejection or complications of immunosuppression

Specific contraindications[a]
- Age >65 years (varies with the program)
- Active infection
- Active ulcer disease
- Severe diabetes mellitus with end-organ damage
- Severe peripheral vascular or cerebrovascular disease
- Coexisting neoplasm
- Morbid obesity
- Creatine clearance <40–50 mL/min, effective renal plasma flow (ERPF) <200 mL/min[b]

Bilirubin >2.5 mg/dL; transaminases >2_normal[c]

Severe pulmonary dysfunction with FVC and $FEV_1$ < ~40% of predicted, especially with intrinsic lung disease

Pulmonary artery systolic pressure >60 mm Hg, mean transpulmonary gradient >15 mm Hg, or pulmonary vascular resistance >5 Wood units[d]
- Acute pulmonary thromboembolism
- Acute diverticulitis
- High risk of life-threatening noncompliance

[a]Contraindications may be either relative or absolute, depending on severity and program preference.

[b]May be suitable for cardiac transplantation if inotropic support and hemodynamic management produce creatinine below 2 mg/100 mL and creatinine clearance above 50 mL/min. Transplantation may be advisable as a combined heart-kidney transplant.

[c]Requires liver biopsy to exclude cirrhosis or other intrinsic liver disease.

[d]Apply only if the increased resistance is largely nonreactive (fixed).

Data from Kirklin JK, McGiffin DC, Pinderski LJ, Tallaj J. Selection of patients and techniques of heart transplantation. *Surg Clin North Am* 2004;84(1):257–287.

demonstrated increased survival without disabling stroke or need for device related reoperation [62 of 134 (46 percent) vs 7 of 66 (11 percent), $p$ <0.001], and improved survival rates at 2 years (58 vs 24 percent, $p = 0.008$).[203] After clinical stabilization of the patient, a complete evaluation for heart transplantation can proceed. In light of the potential for discovery of contraindications to transplantation after emergent placement of a VAD, consideration—including discussions with patients and families—must be given to the potential need to withdraw support in patients who are found to be unsuitable recipients for heart transplantation.

## Outcomes and Prognosis

Survival after CABG for patients in cardiogenic shock or those receiving cardiopulmonary resuscitation (CPR) remains poor; 1- and 10-year survival rates are 59.4 and 47.5 percent.[204] However, these rates compare favorably to medical therapy alone, in which mortality rates in excess of 65 percent at 1 year have been reported.[133] Predictors of poor outcomes after CABG in this population include extent of coronary disease, presence of drug-treated diabetes, and lower arterial pH at entry into the operating room.[204]

## Summary

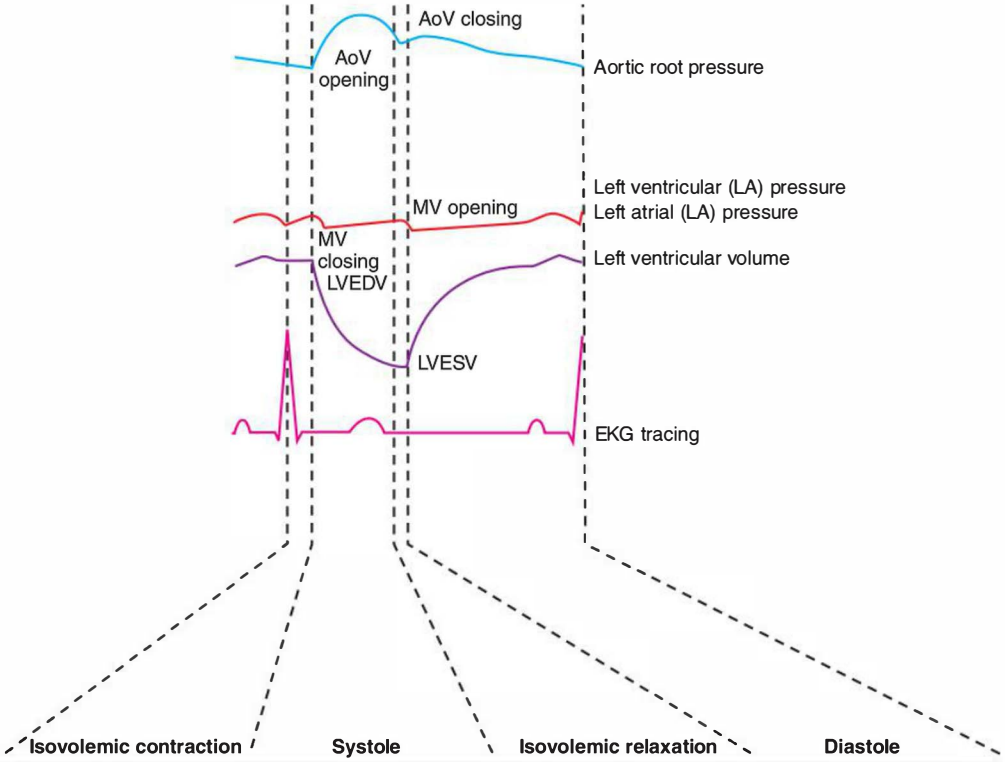
Cardiogenic shock after MI continues to occur in approximately 10 percent of patients who reach the hospital. Though improving slightly, mortality rates remain approximately 60 percent. Patients with hypoperfusion after acute MI should be evaluated rapidly with electrocardiography (ECG), chest x-ray, and echocardiography to determine the cause of shock. In those with cardiogenic shock, therapies should be directed toward stabilization of patients with IV fluid resuscitation, pharmacologic therapy as indicated, and rapid placement of an IABP to support coronary and systemic perfusion. Emergent revascularization with PCI or CABG is associated with improved long-term outcomes. VADs provide an important adjunct to revascularization by supporting circulation through the period of myocardial stunning and providing a bridge to transplantation, and potentially as destination therapy, when appropriate.

# ISCHEMIC MITRAL VALVE DISEASE

## Introduction

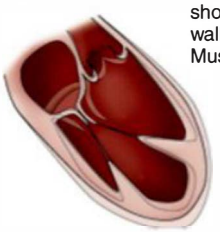
Ischemic mitral regurgitation (IMR) is a disease of the ventricle and papillary muscles (PMs) that leads to valvular dysfunction; by definition, the leaflets and valvular apparatus are normal. The frequent coexistence of nonischemic MV disease and coronary artery disease has led to a poor understanding of the natural history and optimal treatment of IMR. In addition, chronic MR may develop after postinfarct LV dilatation, resulting in annular dilatation[205–208]; this may be difficult to differentiate from "functional" MR resulting from dilated cardiomyopathy. MR occurs frequently after acute MI; precise rates have varied from 8 to 50 percent, depending on the modality used to detect the disease.[209–223] This reflects the heterogeneity of IMR. It ranges from clinically silent disease that is identifiable only on Doppler echocardiography or angiography to severe disease that leads to cardiogenic shock and hemodynamic collapse; it may present acutely within hours of the infarct or develop insidiously over years with worsening congestive heart failure (CHF).

### ANATOMIC CONSIDERATIONS



***Normal Mitral Valve Function.*** Normal MV function requires the coordinated and proper functioning of all components of the valve structure: the valvular leaflets, the annulus, the chordae tendineae, the PMs, the LV wall, and the left atrium (LA). The complex interaction of these components can be analyzed through division of the cardiac cycle into four periods: systole, diastole, isovolemic relaxation, and isovolemic contraction (Fig. 31-6).

***Ischemia and Mitral Valve Components.*** As was noted above, in IMR, the leaflets and annulus usually function normally. The chordae tendineae are also not affected by ischemia. However, the PMs contain functioning myocardium that is dependent on end-artery perfusion and are thus sensitive to ischemic insult. There are two PMs: the anterolateral and posteromedial PMs. The anterolateral PM often is supplied by two arteries, most often the first circumflex marginal artery and the first diagonal branch of the left anterior descending (LAD) artery.[224] Ischemia is uncommon in this location and in the surrounding high lateral wall of the LV because of the extensive collateral system. In contrast, the posteromedial PM lies in the watershed of the right coronary and circumflex arteries and more often is supplied by only a single artery; it is therefore highly sensitive to ischemic insult.[224–226] Variations in PM anatomy may lead to increased sensitivity to ischemia; in particular, narrow PMs supplied by a single central artery are vulnerable to ischemia.[227]



IMR occurs most commonly in association with transmural posteroinferior infarctions.[207,228,229] The location and size of the infarct influence the occurrence and acuity of MR after MI. In a sheep model, ligation of the two most distal circumflex arteries resulted in 21 percent LV mass infarct and gradual development of MR over 8 weeks, ligating the posterior descending artery (PDA) as well increased infarct size to 32 percent and led to immediate MR.[229,230] Similar-sized infarcts in other portions of the heart did not lead to MR.[231]

## Pathophysiology

IMR can be classified broadly into three categories: (1) PM rupture, (2) acute MR, and (3) chronic MR. These conditions result in a variety of disorders of MV function. Carpentier functional categorization of MV dysfunction has been applied

| | Isovolemic contraction | Systole | Isovolemic relaxation | Diastole |
|---|---|---|---|---|
| **Left artium** | LA filling begins after closure of MV | LA rapidly fills, reaching maximum volume near end-systole | LA begins to empty when LA pressure exceeds LV pressure | |
| **Left ventricle** | LA wall thickness increases | LV twists counterclockwise (as viewed from apex)<br>Peak wall thickness occurs near end-systole | LV reverses complex deformation of systole relaxes and dilates LV wall thickness decreases | LV may generate negative pressure |
| **Valve annulus** | | Valve annulus descends 1 to 1.5 cm toward apex<br>Asymmetric contraction of the annulus occurs with minimal valve area near mid-systole | Area of valve annulus increases slightly | Annulus ascends (away from apex) during late diastole |
| **Mitral leaflets** | Flow through the valve briefly reverses with coaptation of the mitral leaflets and bulging into the atrium | | Leaflets separate approximately 30 msec prior to the point where LA pressure exceeds LV pressure | Mitral orifice becomes maximal just prior to onset of atrial contraction<br>Peak blood flow occurs early in diastole prior to maximal valve orifice |
| **Chordae tendinae** | | | Chordal tension decreases rapidly | Chordal tension remains approximately zero until late distole |
| **Papillary muscles** | Papillary muscles begin to shorten | Papillary muscles contract in synchrony with shortening of adjacent LV wall<br>Muscles shorten 2–4 mm | Papillary muscles shorten slightly | Papillary muscles lengthen |

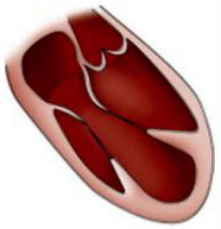


**FIGURE 31-6** Normal mitral valve function requires the coordinated motion of all components of the mitral valve apparatus, including the atrial and ventricular walls. LV, left ventricular; MV, mitral valve; LVEDV, left ventricular end-diastolic volume; LVESV, left ventricular end-systolic volume; EKG, electrocardiogram.

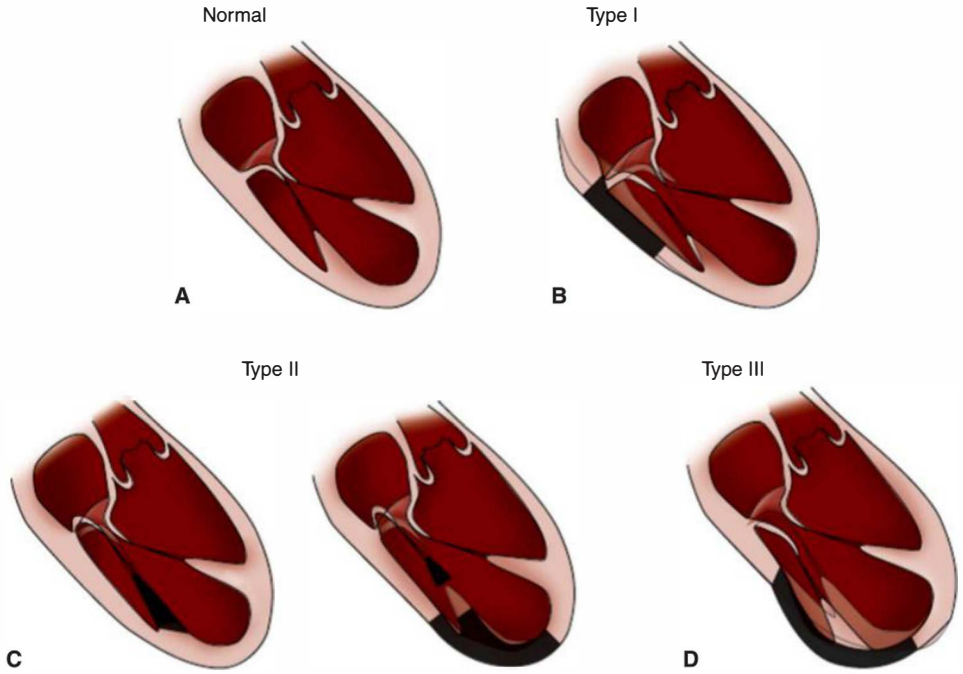

**FIGURE 31-7** Classification of ischemic mitral regurgitation with diagrams of systolic function. **A.** Normal valve function with coaptation of mitral leaflets during systole. **B.** Type I: normal leaflet motion, regurgitation resulting from annular dilatation from ischemia of the adjacent ventricular wall. This results in a central leak. **C.** Type II: prolapsing leaflets. Regurgitation results from either papillary muscle rupture (*left*) in the acute setting or papillary muscle elongation (*right*) secondary to chronic ischemia. This usually results in an asymmetric leak. **D.** Type III: restricted leaflet motion resulting from dysfunction of the ventricular wall and papillary muscle tethering. Type III dysfunction can be sub-categorized as type IIIa and IIIb, depending if there is restricted leaflet opening or closure. This may result in either a central or an asymmetric leak, depending on the nature of the ventricular dysfunction.

to the ischemic MV to guide operative management (Fig. 31-7). In this system, MR is categorized by the derangement in leaflet function: valve dysfunction with normal leaflet motion (type I); excess leaflet motion (prolapsing leaflets) (type II); and restricted leaflet motion during valve opening (type IIIa), or restricted leaflet motion during valve closure) (type IIIb). In the setting of IMR, type I dysfunction occurs when ischemia leads to dilatation of the posterior muscular portion of the valve annulus; this type of deformation may occur with either acute or chronic MR. Type II dysfunction results from PM rupture in the acute setting or may result from chronic ischemia that leads to PM elongation. Type IIIa restricted leaflet opening occurs in the setting of chordal or commissural thickening or fusion; type IIIb restricted leaflet closure occurs in the setting of calcification with ventricular aneurysm or dilatation.

## PAPILLARY MUSCLE RUPTURE

Rupture of PMs results in a loss of leaflet tethering, leading to flail mitral leaflets and MR (Carpentier type II). The more commonly affected posteromedial PM consists of one or two large common trunks and multple heads, all of which give off chordae tendineae to both the anterior and the posterior leaflets of the MV. Acute complete rupture of the common trunk leads to massive MR and hemodynamic collapse. In contrast, partial rupture of the common trunk or rupture of one of the heads may lead to more moderate (and better tolerated) regurgitation.[232] However, partial rupture may progress to complete rupture, leading to subsequent acute decompensation.[233,234]

## ACUTE MITRAL REGURGITATION

When not associated with PM rupture, acute MR results from discoordination of the MV complex. Traditionally, it was thought that PM dysfunction, which is caused by poor systolic shortening of the ischemic PM, leads to MV prolapse and regurgitation in the acute setting. However, studies have not demonstrated MV prolapse in acute IMR.[235,236] Loss of PM systolic shortening alone does not account for the MR seen after MI. Rather, dysfunction of the LV wall resulting from myocardial ischemia with hibernation or stunning or from infarction may lead to failure of valve coaptation. Depending on the location of the infarct, this may result primarily from annular dilatation (Carpentier type I), as was demonstrated by Miller's group, among others,[207,237,238] or by changes in the interaction between the ischemic and nonischemic PMs during systolic contraction, leading to PM tethering and restricted leaflet motion (Carpentier type IIIb).[230,239,240] When not repaired in the acute phase, MR unrelated to PM rupture may disappear, remain unchanged, or become more severe.[241]

### CHRONIC MITRAL REGURGITATION

Chronic IMR also results from a complex of abnormalities in the valvular apparatus. However, in constrast to acute MR, in which changes may be small and difficult to visualize with current imaging techniques, chronic MR usually results in larger changes that are easily apparent on echocardiography. Although some authors have described lengthening of the PM resulting in MV prolapse (Carpentier type II),[206,242] pathologic studies suggest that PM atrophy and scarring are more common.[229,235,243] This results in leaflet tethering during systole, preventing proper coaptation. This phenomenon has been observed in animal models.[244] LV remodeling in general and dilatation in particular (resulting in both dislocation of the PM apically and laterally and dilatation of the valve annulus) further contribute to leaflet tethering through apical displacement of the PM during systole.[245–249] Three-dimensional (3-D) modeling of changes in MV and ventricular function demonstrates that all these changes—posterior PM displacement, annular dilatation, and apical restriction of the posterior leaflet—are associated with the development of IMR (Fig. 31-8).

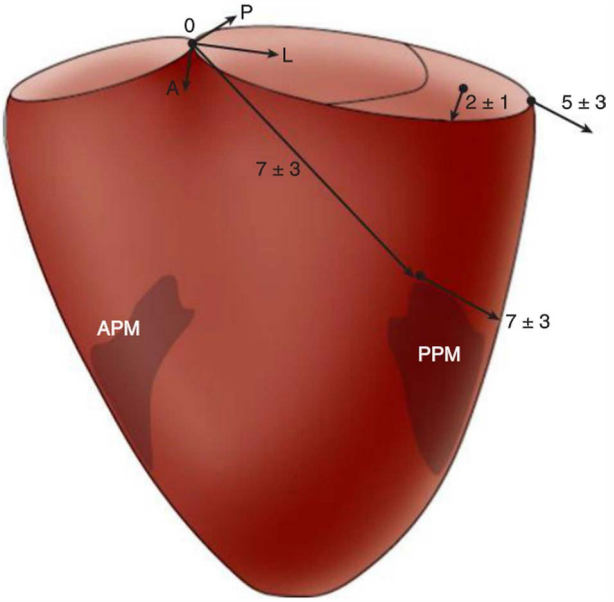

**FIGURE 31-8** Comparison of ischemic changes in mitral valve geometry with and without mitral regurgitation in an ovine model. Arrows represent changes from baseline in the group of animals developing mitral regurgitation that were significantly different from changes occurring in animals that did not develop regurgitation despite similarly located and sized infarcts. Animals developing ischemic mitral regurgitation had more severe displacement of the posterior papillary muscle, septal–lateral dilatation of the annulus, and apical tethering of the posterior leaflet. APM, anterior papillary muscle; PPM, posterior papillary muscle. (From Tibayan FA, Rodriguez F, Zasio MK, et al. Geometric distortions of the mitral valvular-ventricular complex in chronic ischemic mitral regurgitation. *Circulation* 2003;108(Suppl 1):116–121.)

Ideally, operative therapy should be directed toward the causes of MR in each patient. When tethering and apical displacement are responsible for poor leaflet coaptation (Carpentier type IIIb), lengthening of the PM theoretically should ameliorate MR by displacing the attachment points of the chordae toward the valve. In contrast, when annular dilatation is the primary abnormality (Carpentier type I), MV repair with a ring annuloplasty is the most appropriate surgical option.

### EPISODIC ISCHEMIC MITRAL REGURGITATION

A small but important subset of patients may present with chronic *episodic* MR. Patients with this entity develop episodes of dyspnea or flash pulmonary edema with or without associated angina.[250] The murmur of MR will appear during these episodes and subsequently resolve during asymptomatic periods.[251] In these patients, MR is an anginal equivalent caused by transient ischemic dyskinesia of the LV wall that results in apical displacement of the mitral leaflets (Carpentier type IIIb).[252] Because the regurgitation is caused by ischemia of the ventricular wall, treatment should be directed toward ischemia rather than MV function; revascularization without MV surgery should be performed.

## Clinical Features

### PAPILLARY MUSCLE RUPTURE

PM rupture usually leads to acute and rapid hemodynamic collapse with massive MR. Severe pulmonary edema is almost invariably present. It occurs a median of 1 day (and nearly invariably within 14 days) after the onset of infarction.[253] The murmur of MR (a holosystolic murmur best heard over the apex) may be mild or absent. This probably is due to three factors: (1) The wide regurgitant orifice causes a minimum of turbulence; (2) the pressure gradient between the LA and the LV normalizes rapidly, reducing turbulence, and (3) the auscultatory findings of severe pulmonary edema may mask the murmur entirely.[254–256] PM rupture is a rare (occurring in 0.3 to 5 percent of patients with acute MI)[233,257,258] but devastating complication of MI. Mortality rises rapidly in patients with PM rupture: 50 percent at 24 h and 75 percent at 48 h.[233] Median survival in medically managed patients ranges from 1 to 4 days in various series.[233,234]

### ACUTE AND CHRONIC MITRAL REGURGITATION

Depending on the severity of MR that occurs in association with MI, the presentation may range from a new murmur to severe pulmonary edema. Patients who present with mild asymptomatic MR acutely after an MI may be managed as if the MR were not present. When it is not related to PM rupture, acute MR becomes apparent a median of 7 days after infarction.[234,253] However, a subset of patients (approximately 0.1 percent of those with symptomatic coronary disease) will develop acute severe MR.[259] These patients invariably

require surgery for survival. Patients present with symptoms of acute coronary syndromes, including acute onset of chest pain and/or shortness of breath. Pulmonary edema, systemic hypotension, and ultimately cardiogenic shock may ensue rapidly.

As was noted above, infarct size may affect the acuity of the presentation, with chronic MR resulting from smaller LV infarcts. Unlike organic MR,[260] the murmur of IMR correlates poorly with the severity of the regurgitant volume, partly as a result of the low flow present in an ischemic heart.[261] In addition, as many of 50 percent of patients with moderate or severe MR may be missed on physical examination alone.[214] Therefore, even low-intensity murmurs in patients who present with acute MI should be investigated to rule out MV pathology, especially in patients in whom cardiogenic shock or pulmonary edema is associated with well-preserved LV function.[254,261]

The literature on chronic IMR is confounded by the inclusion of patients with nonischemic organic mitral disease in most large series. However, patients with MR appear to have more severe CHF and are more likely to have renal failure than are those without MR.[262] Data from the Cleveland Clinic excluded patients with nonischemic MR. Of the 482 patients undergoing isolated MV surgery for IMR, 80 percent had chronic MV disease. Although separate analyses were not performed for that population, heart failure was common, with 32, 30, and 36 percent of patients in New York Heart Association (NYHA) class II, III, and IV functional status, respectively.[228]

Overall, MR is found in 15 to 20 percent of patients after MI.[214,216] Multiple investigators have demonstrated the association between MR in the setting of acute MI and poor outcomes.[213,263] Barzilai and associates showed a two-fold increase in mortality (36 vs 15 percent), but that difference disappeared when it was controlled for comorbid conditions.[263] More recent studies, however, though confirming the association between MR and multiple predictors of poor outcomes (including older age, multivessel disease, and severe LV dysfunction),[214,216] have shown an independent effect of MR on cardiovascular mortality. In the 727 patients involved in the Survival and Ventricular Enlargement (SAVE) study, the presence of mild or moderate MR was associated with a two-fold increase in cardiovascular mortality in multivariate analysis (median follow-up 3.5 years).[216] Tcheng and colleagues found a similar effect at 1 year (odds ratio 1.5) in patients with moderate or severe MR.[214] Grigioni and associates found that the degree of MR [as measured by estimated regurgitant orifice (ERO)] correlated with mortality in a population of 303 patients operated on more than 16 days after MI with either mitral repair or replacement (risk ratio for ERO less than 20 $mm^2$ 1.65; for ERO equal to or greater than 20 $mm^2$ 2.23).[264] Similar results were seen in a series of 4221 patients undergoing PCIs remote from an MI; the 53 patients with moderate or severe MR had 3-year survival of 68.6 vs 92.3 percent for those without any MR.[262] This difference was even more pronounced among those with a LVEF less than 40 percent. Similarly, in the SHOCK trial, both severe MR and depressed LVEF were predictors of increased 1-year mortality regardless of treatment assignment.[26]

In summary, ischemic MV disease consists of a spectrum of clinical presentations that ranges from acute to chronic and from mild to severe. However, it is associated with poor outcomes regardless of severity.

## Diagnostic Modalities

### ECHOCARDIOGRAPHY

Echocardiography provides useful diagnostic and prognostic information in both acute and chronic MR. Acutely, transthoracic echocardiography (TTE) is the diagnostic study of choice in evaluating patients with hemodynamic instability after MI. TTE enables the detection of wall motion abnormalities, quantitation of the degree of MR, and assessment for other mechanical causes of circulatory collapse, including septal or free wall rupture; it also may demonstrate flail mitral leaflets or other evidence of PM rupture. The preoperative TTE should be used in planning intervention on the MV as intraoperative transesophageal echocardiography (TEE) often underestimates the amount of regurgitation.[265]

When TTE does not provide adequate information about PM integrety, TEE may be required; some authors recommend routine TEE because of the failure of TTE to detect MR and PM rupture in up to 80 percent of patients.[257] Because of the high mortality rate associated with PM rupture without operation, detection of this uncommon complication as part of the evaluation of patients with MI is imperative. Traditionally, PM rupture was identified by locating a mobile mass attached to the mitral leaflet prolapsing into the right atrium; however, even with TEE this may fail to detect PM rupture in as many as 35 percent of patients; a complete evaluation of the LV is also necessary to evaluate for large-amplitude erratic motion of the PM head in the LV that is indicative of rupture (Fig. 31-9).[226]

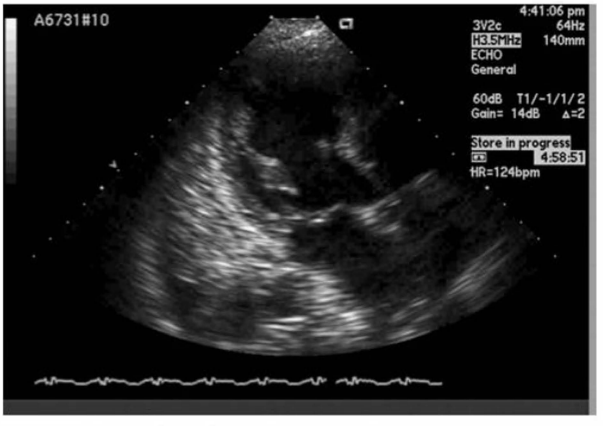

**FIGURE 31-9** Echocardiography of mitral regurgitation caused by papillary muscle rupture with mobile mass attached to the mitral leaflet.

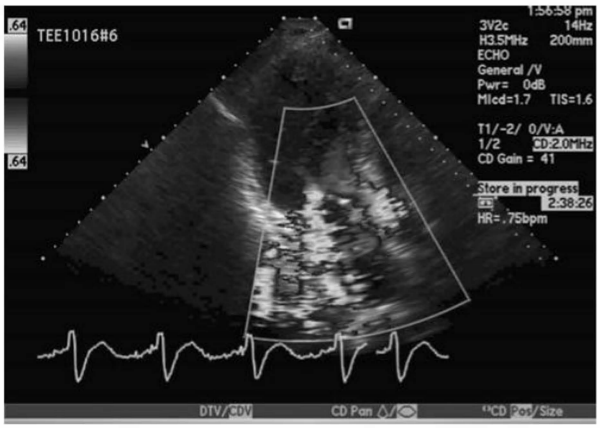

**FIGURE 31-10** Echocardiography of mitral regurgitation demonstrating regurgitant jet using Doppler imaging.

In chronic MR, echocardiography can be used to follow progression of disease as well as distinguish ischemic from organic pathology. Doppler echocardiography allows identification and quantification of mitral regurgitant flow (Fig. 31-10), and two-dimensional echocardiography can be used to examine LV structure and identify abnormalities in leaflet and chordal morphology and function. TEE is superior to TTE in the evaluation of valvular pathology, particularly in identifying sequelae of endocarditis such as vegetations, leaflet perforations, and inflammatory changes.

### ANGIOGRAPHY

The increased diagnostic accuracy of echocardiography has allowed it to replace angiography in the assessment of MR. Thus, angiography remains clinically useful primarily in delineating coronary anatomy and treating stenotic lesions when appropriate. Despite hemodynamic instability, most patients who present with MR in association with acute MI will receive an angiogram.

In chronic MR patients, a preoperative angiogram also is used to delineate coronary anatomy and plan the operative procedure and approach. Measurement of intracardiac and intravascular pressures as well as cardiac output assists in the assessment of LV function. However, in light of the high incidence of renal failure in this population,[228] a ventriculogram should be avoided because it provides little information beyond that obtainable by echocardiography.

## Medical Therapy

### ACUTE MITRAL REGURGITATION

Therapies directed at patients with acute MR after MI depend largely on the degree of regurgitation and the patient's hemodynamic status. In most patients, the presence of MR will not affect the management of acute infarction; however, a minority of patients will develop 3+ or 4+ MR with heart failure and cardiogenic shock. These patients with acute severe MR should be admitted to the intensive care unit (ICU) until definitive therapy (surgery or, catheter-based interventions) can be instituted.

Diagnostic studies should be initiated to determine the cause of the decompensation; patients with PM rupture in particular must receive rapid operative therapy. In the ICU, patients should have advanced cardiac monitoring. Fluid resuscitation should be directed by measurements of cardiac filling as both hypovolemia and volume overload may impair cardiac function significantly. Patients in cardiogenic shock may require inotropic therapy and, when inotropic therapy is inadequate, an IABP may be helpful. In the setting of MR, an IABP has been shown to decrease the regurgitant fraction and increase systemic cardiac output and carotid blood flow, all without changing LV function.[266]

Telemetry monitoring should be used to assess for arrhythmias, which are common in postinfarction MR. The antiarrhythmic agents used should be those least likely to cause hypotension or impair myocardial contractility. Electrical cardioversion may be the best choice for patients with tachyarrhythmias, and transcutaneous or transjugular pacing may be required to control bradyarrhythmias in this setting.

### CHRONIC MITRAL REGURGITATION

A variety of pharmacologic agents are available for treating patients with chronic MR. Vasodilators and ACE inhibitors or angiotensin-1 (AT1) receptor blockers improve LV volume and decrease the regurgitant fraction through a reduction in afterload. However, no trial has demonstrated an improvement in survival with these treatments. In patients with LV systolic dysfunction, β-blockers have a positive effect on ventricular remodeling and the ejection fraction and have been shown to reduce the volume of MR. Combined use of vasodilators and β-blockade may be particularly useful in patients with MR and LV dysfunction.

## Surgical Therapy

### OPERATIVE INDICATIONS

***Papillary Muscle Rupture.*** Surgery is the only effective therapy for PM rupture. Although mortality rates are high,[267,268] the rates for nonoperative management are higher. Depending on the location of the rupture, different operative techniques may be indicated. In the setting of PM trunk rupture, MV replacement is recommended. When rupture of the PM head occurs but the adjacent head and body remain viable, repair of the PM may be an option. However, these repairs should be attempted only when the patient's clinical condition allows. Commonly, PM rupture combined with ongoing cardiac motion leads to entanglement of the muscle within the other chordal structures; complete disentangling must be performed before repair to preserve ventricular and valvular function.[269] When the clinical situation

does not allow for repair of the PM, MV replacement should be performed.

***Acute Mitral Regurgitation.*** Most patients with acute MR after MI are managed with medical therapy and PCI. However, in addition to those with PM rupture, at least four subsets of patients may require operative therapy in the acute setting: (1) patients with coronary artery disease requiring surgical revascularization, (2) patients with acute postinfarct angina, (3) patients with acute postinfarction angina and 1+ to 2+ MR, and (4) those with acute severe MR in association with progressive heart failure and cardiogenic shock.

Patients in whom percutaneous intervention does not achieve adequate revascularization and those with important left main or severe three-vessel coronary artery disease require surgical intervention. Revascularization should be performed first in this population; if postbypass echocardiography continues to demonstrate significant (2+ or greater) MR, valve repair or replacement should be performed.

Individuals with postinfarct angina should be managed initially with emergent medical or percutaneous revascularization to relieve angina and prevent extension of the infarct, which might result in heart failure, worsening MR, and cardiogenic shock. Although CABG rarely is completed in time to prevent reinfarction in patients with postinfarct angina, it may decrease eventual infarct size.[270–272] In these patients, exposure of the MV should not be performed unless intraoperative TEE demonstrates 3+ or 4+ MR.

Patients with acute severe MR with hemodynamic instability require emergent revascularization, usually surgical. Although there have been reports of resolution of MR with thrombolysis alone, the results have been inconsistent.[214,217,273,274] Rapid (within 4 h of symptom onset) percutaneous revascularization also has demonstrated occasional dramatic resolution of severe MR in settings where viable myocardium remains in the distribution of the culprit artery.[214,274,275] However, even with successful medical or percutaneous revascularization, mortality rates remain high, and most of these patients continue to have 3+ to 4+ MR.[276]

Indications for operative management of acute severe MR vary between institutions but include pulmonary edema, LV failure, and failure of nonsurgical revascularization to abolish MR; the urgency of MV management depends on the presence or absence of cardiogenic shock.[276] In these patients, medical therapy alone has nearly universal mortality.[234,277,278] Operation for acute severe MR should consist of valve repair or replacement with or without myocardial revascularization.

Both mitral valve repair (MVr) and mitral valve replacement (MVR) are options in these patients. Although long-term results appear to be similar within matched cohorts,[228,279] patients undergoing repair for acute severe MR have higher reoperation rates as a result of valve failure.[279] The difficulty of assessing the viability and long-term strength of the valvular apparatus may play a role in these failure rates. During replacement, whether mechanical or biological prosthetic valves are chosen, it is important to preserve chordal attachments to preserve LV geometry.[280]

Bypass grafts should be placed to revascularize all significantly obstructed coronary vessels that are remote from the infarct. Although the survival benefit of revascularization of the infarct-related artery after more than 4 to 6 h of symptoms is not clear, even in completed infarctions revascularization appears to improve LV remodeling.[271,272,281] In contrast, blind revascularization of coronary arteries in patients without preoperative angiograms is not likely to be of benefit: Fewer than 50 percent of patients with acute severe MR have multivessel disease,[277,282] and a prolonged operation may increase mortality further in this critically ill population.

***Chronic Mitral Regurgitation.*** Patients with chronic MR after MI form the largest group of patients who require MV surgery for ischemia. Patients who require surgical revascularization may have MR that ranges from mild to severe with a corresponding range of symptoms (Fig. 31-11).[283] At the ends of this spectrum, management of patients is relatively clear. In those with only trace or mild MR and few symptoms of heart failure, CABG alone should be performed; in

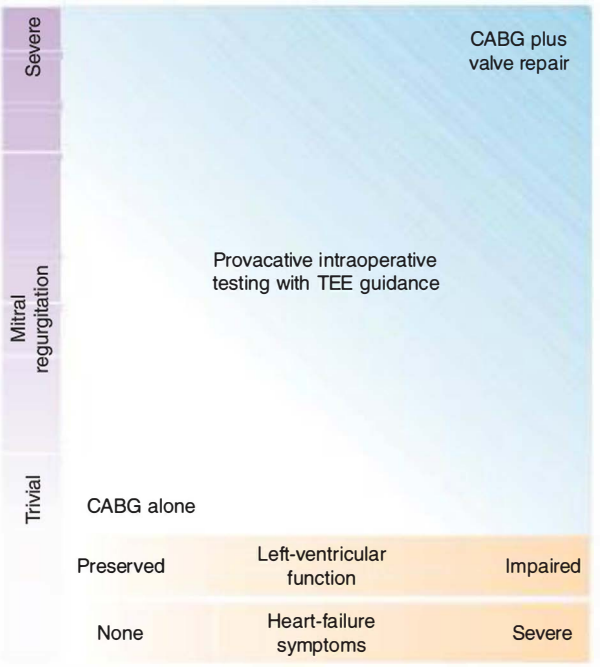

**FIGURE 31-11** Diagram of operative management of chronic mitral regurgitation. Patients with minimal mitral regurgitation and good ventricular function should be managed with CABG alone; those with severe ventricular dysfuction and severe MR warrant mitral valve surgery. Management of patients falling in the intermediate area remains controversial. CABG, coronary artery bypass grafting; MR, mitral regurgitation. (From Byrne JG, Aklog L, Adams DH. Assessment and management of functional or ischaemic mitral regurgitation. *Lancet* 2000;355(9217):1743–1744.)

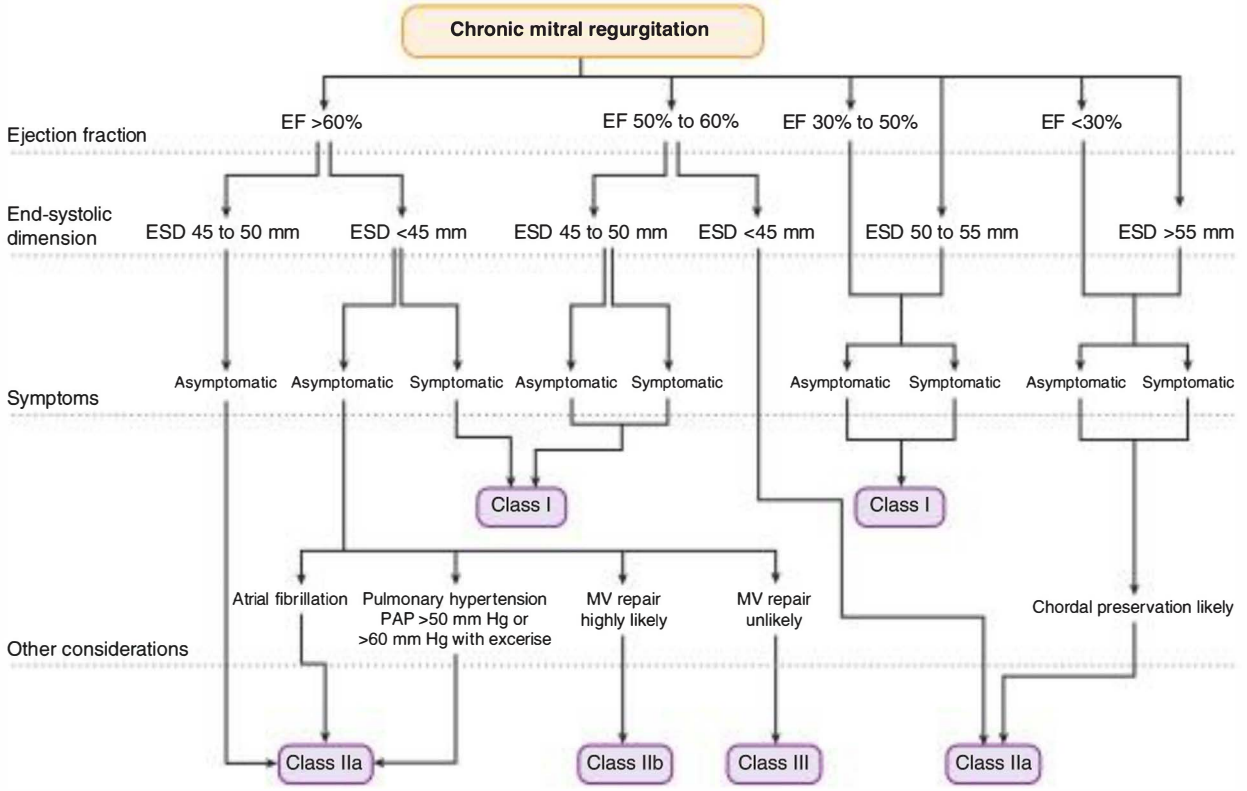

**FIGURE 31-12** Flowchart indicating recommended management of chronic nonischemic mitral regurgitation or chronic ischemic mitral regurgitation without viable myocardium for reperfusion therapy. Class I, evidence and/or agreement that surgery is useful and effective; class IIa, divergence of opinion: weight of evidence/opinion favors usefulness; class IIb, divergence of opinion: usefulness less well established; class III, not indicated or harmful. [Based on the recommendations of the American College of Cardiology/American Heart Association as published in Bonow RO, Carabello B, de Leon AC, et al. ACC/AHA Guidelines for the Management of Patients with Valvular Heart Disease: Executive Summary: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Management of Patients with Valvular Heart Disease). *J Heart Valve Dis* 1998;7(6):672–707.]

those with severe (3+ to 4+) MR and significant sequelae, concomitant MV surgery is indicated.

Management of patients in the middle of this spectrum remains controversial, with few data to guide therapy. Some series suggest that long-term outcomes in these patients are equivalent whether CABG or CABG with MV surgery is performed.[284] However, CABG alone does not treat MR,[285] and MR even of only mild or moderate severity has been associated with increased long-term mortality.[216,264] Intraoperative assessment of MV function in these patients should include preload and afterload challenges to mitigate the unloading effects of general anesthesia.[205,228,286,287] If provocative testing fails to unmask significant (3+ or 4+) MR or if the resultant MR is associated with focal wall motion abnormalities from the development of ischemia, CABG can be performed without inspection of the MV. However, if these tests demonstrate regurgitation, MV repair or replacement should be considered.

Some patients with IMR may not have viable myocardium that is amenable to surgical revascularization. In these patients, indications for surgical intervention are the same as those for patients with functional nonischemic regurgitation (Fig. 31-12). In contrast to patients undergoing concomitant CABG and valve surgery, in this population the increased afterload after MV surgery is not balanced by improved ventricular function after revascularization; therefore, operative intervention may be poorly tolerated, and many patients may go on to require heart transplantation.

## PERIOPERATIVE CONSIDERATIONS

***Acute Severe Mitral Regurgitation.*** Overall surgical management of these patients is similar to the management of those with cardiogenic shock in the absence of MR (see above). CPB should be initiated via direct cannulation of the ascending aorta and bicaval cannulation via the right atrium. Bicaval cannulation maintains decompression during the mitral repair, particularly when exposure of the MV causes superior vena caval obstruction. After aortic cross-clamping and myocardial protection via retrograde and antegrade cardioplegia, the LA is opened. The distal coronary arteries

should be grafted before valve surgery. It is important to ensure that all grafts are secure before beginning the valve surgery, as it may be difficult or dangerous to retract the heart after implantation of the prosthetic ring or valve because of the risk of dehiscence or LV rupture.

***Chronic Mitral Regurgitation.*** Preoperative preparation in these patients is similar to that for other cardiac operations. The surgical approach and the institution of CPB are the same as those described for acute MR and include bicaval cannulation, the use of retrograde and antegrade cardioplegia, and the construction of arterial grafts before the valve procedure. After the induction of anesthesia, the MV should be assessed carefully with TEE to evaluate whether valve surgery is required; if doubt exists, provocative testing should be performed after placement of the arterial cannula.

## OPERATIVE TECHNIQUE

***Repair of Rupture of the Papillary Muscle Head.*** Double-armed, pledgeted 4-0 polypropylene sutures are passed through the viable PM trunk and then into the PM head, where another pledget is used to buttress the knot (Fig. 31-13). The addition of gelatin-resorcinol-formalin glue may help strengthen the repair.[276] In the case of avulsion of the primary chordae, chordal transfer may be performed with a segment of posterior chord. Alternatively, new artificial chordae constructed from extended polytetrafluoroethylene (ePTFE) sutures may be used.[288]

***Mitral Valve Repair vs Replacement.*** The use of repair vs replacement in IMR remains controversial. Because randomized studies are not available to answer this question, large retrospective cohorts provide the only guidance. Gillinov and associates recommend valve repair in most patients. Among the low-risk matched cohorts, MVr had a trend toward improved short- and long-term survival (30-day, 1-year, and 5-year survival 94, 82, and 58 percent vs 81, 56, and 36 percent).[228] However, in the high-risk group, outcomes were similar.[228] When MVr was performed, outcomes were improved with the use of internal thoracic artery graft and the use of a formal annuloplasty band or ring (rather than a pericardial strip).[228] Grossi and associates reported similar results with repair.[279] Patients who may benefit from replacement rather than repair include elderly patients with severe LV dysfunction who may not tolerate a prolonged operation[276] and patients with severe ventricular and PM dysfunction that causes significant type III regurgitation. In these patients, repair may not lead to functional coaptation of the mitral leaflets.[228,261,279] Most authors strongly favor repair in the majority of patients with IMR, citing over 90 percent freedom from operation.[289] In examining over 3,000 patients, Galloway et al. report 93 ± 1 percent freedom from reoperation at 8 years for minimally invasive MVr.[290] Whichever surgical treatment is preferred, careful inspection of the valve should be performed after cardiotomy to identify abnormalities in the PMs and chordae as well as defective leaflet tissue to direct appropriate therapy.

**FIGURE 31-13** Illustration of reimplantation of the ruptured papillary muscle head onto the trunk of the viable adjacent papillary muscle. (Adapted from Fig. 32-8 in Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 1998.)

***Chordal-Sparing Mitral Valve Replacement.*** Chordal sparing techniques should be used for valve replacement in all patients with IMR. This can be performed by securing the chordae to the valve annulus as described by Khonsari and colleagues (Fig. 31-14).[276] This technique permits resuspension of the chordae with preservation of subvalvular anatomy while allowing for sufficient resection of the anterior leaflet to avoid obstruction of the left ventricular outflow tract (LVOT). The anterior leaflet is excised, and the rim of leaflet containing the chordal attachment is reattached to the anterior annulus with pledgeted sutures (Khonsari I) (Fig. 31-14A). When the leaflet is calcified, it may be necessary to subdivide the leaflet into two to four segments and reattach each segment to the annulus in an anatomic fashion. If the anterior leaflet is soft and pliable, a central ellipse may be excised and the leaflet free edge may be reattached to the annulus (Khonsari II) (Fig. 31-14B). The posterior leaflet can simply be plicated using horizontal mattress sutures to secure the chordal-leaflet junction to the posterior annulus. The stitches should be placed through the chordal-leaflet junction to elevate the chordae to the level of the valve and preserve the chordal contribution to normal LV geometry as much as possible (Fig. 31-14C).

The decision to use bioprosthetic or mechanical valves should be individualized to the patient on the basis of life expectancy and the risks of anticoagulation. Patients at high risk for anticoagulation or with a life expectancy less than 5 or 6 years are candidates for bioprosthetic valves at most centers.

***Mitral Valve Repair.*** A wide variety of techniques for MVr have been reported; however, 98 percent of patients in the

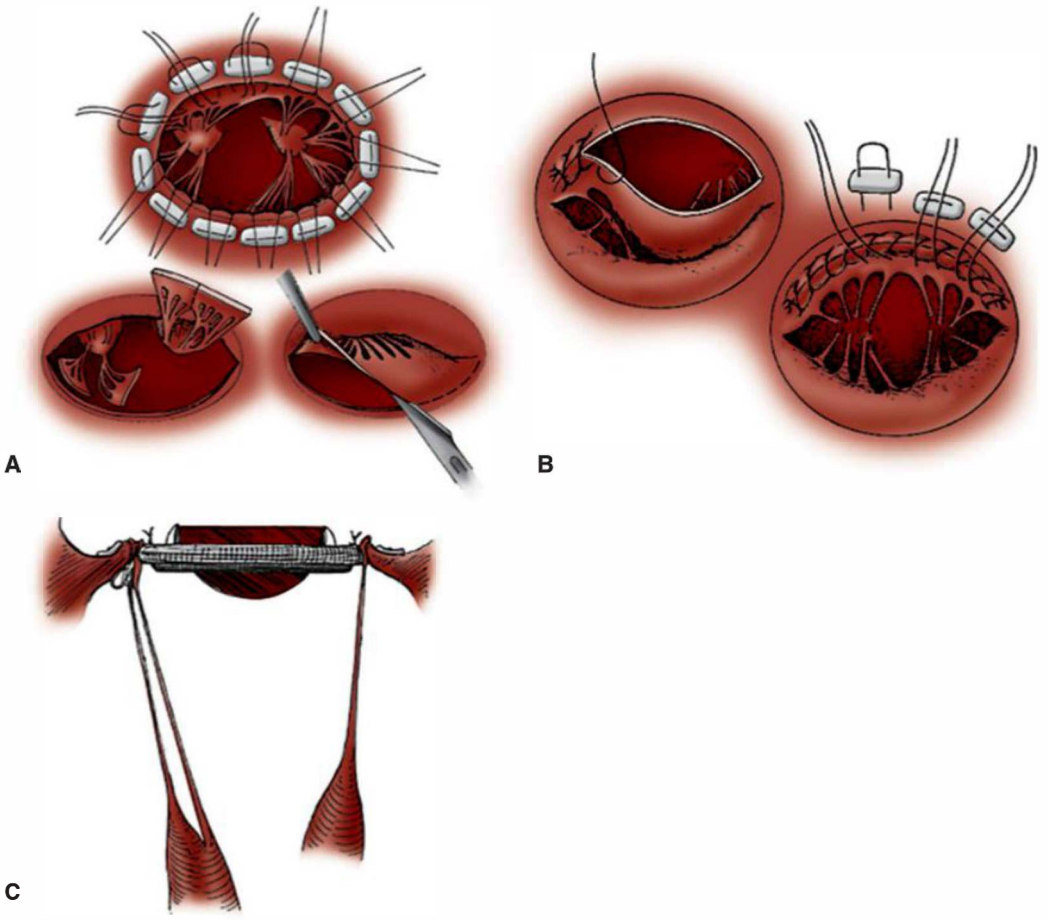

**FIGURE 31-14** Illustration of techniques for chordal preservation during mitral valve replacement. **A.** Khonsari I technique. The anterior leaflet is excised from the annulus while preserving the leaflet–chordal junction. The leaflet then is divided if necessary, and the chordae are resuspended in their normal anatomic positions surrounding the annulus. **B.** Khonsari II technique. When the valve leaflet is soft and pliable (as is common in ischemic mitral regurgitation), a central ellipse of the anterior leaflet is excised, and the free edge is reattached to the annulus, using the valve sutures. **C.** Cross-sectional image. The relationship of the excised anterior leaflet and plicated posterior leaflet to the valve structure is clearly indicated. (Adapted from Fig. 34-10 through 34-12 in Kaiser LR, Kron IL, Spray TL (eds). *Mastery of Cardiothoracic Surgery*. Philadelphia: Lippincott-Raven, 1998.)

study by Gillinov and associates[291] underwent annuloplasty, and this is the most common and most consistently effective method. Sizing of the valve should be performed as with standard MV surgery, using the intertrigonal distance and the area of the anterior leaflet; an undersized annuloplasty is generally preferred. In the Gillinov series, 79 percent of patients had annuloplasties of less than 30 mm, and other series have reported excellent results using undersized annuloplasty for MVr.[228,286,287] Both complete annuloplasty rings and posterior annuloplasty bands have been used, and the results appear similar.[228] However, the additional time required for insertion of a complete ring argues against their continued use.

The annuloplasty ring is sutured into place with 2-0 Dacron horizontal mattress sutures from the left fibrous trigone to the right fibrous trigone along the LV free wall (Fig. 31-15).[276] The sutures should be spaced so that the medial 50 percent of sutures are placed into only 40 percent of the circumference of the annuloplasty ring; this plicates the medial aspect of the annulus and enhances leaflet coaptation.[276] Suture annuloplasty has been reported to enhance coaptation of the leaflets, as has commissuroplasty. Although suture annuloplasty is simple and rapid, the long-term results are poor. Commissuroplasty has significant disadvantages, including instability, partial dehiscence, and the potential to narrow the MV.[276]

Postrepair intraoperative TEE is essential to the operative management of patients undergoing MVr, and its use is associated with improved long-term outcomes after repair.[291] The degree of MR on intraoperative TEE correlates well with early and late postoperative results.[292,293] Although trace to mild residual MR is frequently present and is not associated

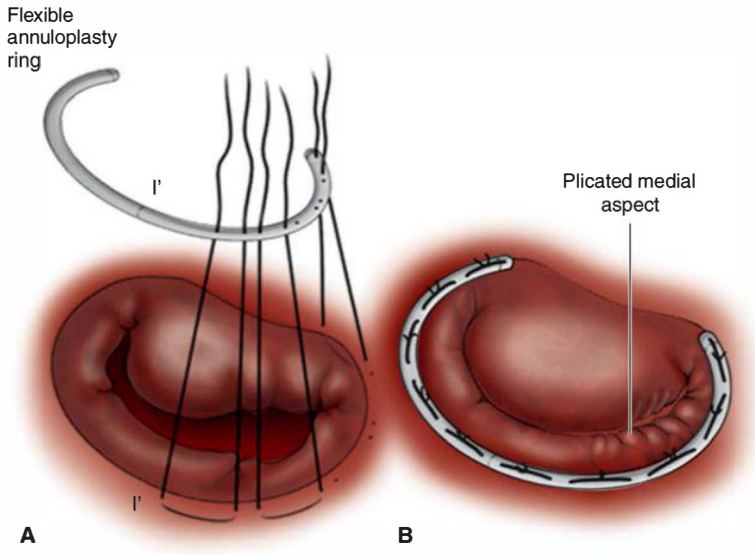

**FIGURE 31-15** Placement of a flexible annuloplasty ring for mitral regurgitation. **A.** The sutures are placed into the annulus in an asymmetric manner so that 50 percent of the sutures along the medial aspect are placed into only 40 percent of the annuloplasty ring. **B.** This results in preferential plication of the region of the posteromedial commissure and enhances coaptation between the anterior and posterior leaflets. (Adapted from Fig. 23.8A and B in Buxton BF, Frazier OH, Westaby S (eds). *Ischemic Heart Disease Surgical Management*. Philadelphia: Mosby, 1999.)

with decreased survival, it portends a higher reoperation rate.[294] Moderate to severe residual regurgitation at discharge is associated with poor long-term survival[295] and, when identified intraoperatively, necessitates a return to CPB and reevaluation of the valve. Redo of the repair has been successful in some populations,[296] but in patients undergoing prolonged procedures with concomitant CABG valve replacement it should not be delayed. In large series, reinstitution of bypass and redo of the valve surgery are required in approximately 2 to 7 percent of cases.[297,298]

In addition to identifying residual MR after repair, TEE is important in detecting dynamic LVOT obstruction caused by systolic anterior motion (SAM) of the anterior mitral leaflet into the LVOT (Fig. 31-16). A variety of factors are associated with the development of SAM after MVr: excessive anterior leaflet tissue, increased posterior leaflet height, a hyperkinetic heart, a prominent interventricular septum, a narrow aortic-mitral angle, too small an annuloplasty ring or inaccurate ring orientation, and extensive quadrangular resection of the posterior leaflet.[299] In general, these factors bring leaflet coaptation and the anterior leaflet closer to the septum, resulting in LVOT obstruction. In early series, SAM occurred in approximately 5 to 10 percent of cases of MVr.[300,301] Improvements in operative technique (including the sliding leaflet technique of Carpentier[302,303]) have reduced this incidence in more recent series secondary to reduction in the height of the posterior leaflet.

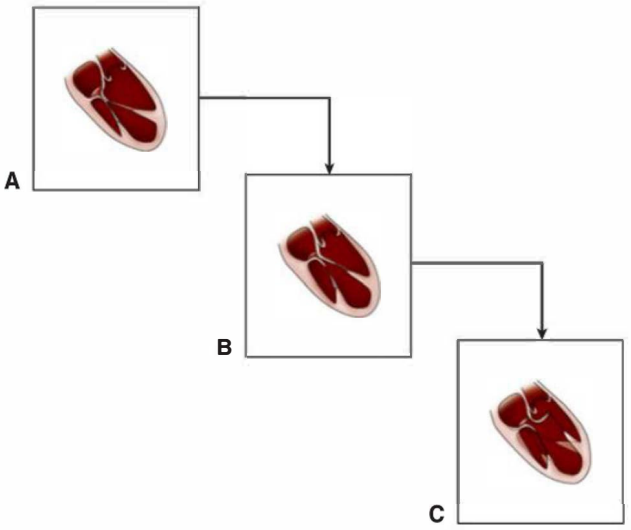

**FIGURE 31-16** Systolic anterior motion of the anterior mitral leaflet and left ventricular outflow tract (LVOT) obstruction. **A.** Normal heart in systole. **B.** Displacement of the anterior mitral leaflet toward the ventricular septum and into the LVOT may be precipitated by the posterior portion of the annuloplasty ring pushing the anterior leaflet too far forward, excessive shortening of chordae or papillary muscles during the operative procedure, left ventricular hypertrophy, or a variety of other factors. **C.** Intermittently, the mitral leaflet may get drawn into the LVOT, causing dynamic obstruction and sudden onset of hypotension.

On TEE, SAM can be seen as protrusion of the free edge of the anterior leaflet into the LVOT. It often is associated with deviation of the coaptation point toward the septum as well as a small left ventricle and a bulging septum.[304] Changes in LV geometry with changes in volume status may play a significant role in the development and presentation of SAM; therefore, not all patients will have abnormal postrepair TEEs. In these patients, the postoperative onset of SAM and LVOT obstruction may be heralded by a rapid onset of hypotension, near syncope, and arrhythmias.[304]

The initial treatment of SAM should be directed at optimization of LV volume to displace the anterior leaflet away from the septum. The use of inotropes should be minimized to reduce hyperdynamic LV contractility. Phenylephrine may be used to increase SVR; the reflex bradycardia increases LV size through an increase in diastolic filling.[299] β-blockade may be useful in increasing diastolic filling as well as treating superimposed tachyarrhythmias.[304] Finally, initiation of AV pacing and adjustment of the pacing intervals have eliminated SAM in some cases.[299] With an appropriate repair, most patients will respond to medical therapy alone,[301] but patients who require large alterations in hemodynamics with phenylephrine and β-blockade should be considered for revision of the MVr or MVR.

***Other Techniques.*** Because annuloplasty and other techniques of MVr do not address the pathology of IMR (which involves dysfunction of the LV wall that leads to failure of leaflet coaptation), attempts have been made to address IMR at the ventricular level. Two techniques have been validated in animal models but have not been evaluated in humans. LV remodeling through plication of the infarct region reduces the distance between the PMs and the mitral annulus; this reduces systolic tenting and decreases the regurgitant volume.[305] A reduction in tenting and an improvement in MR were noted with selective cutting of a limited number of basal chordae tendineae involved in incomplete valve closure.[306] The applicability of these techniques in humans remains to be seen.

Percutaneous valvotomy and valve repair are evolving technologies for use in high risk patients. A number of technologies for percutaneous MV repair are being developed. The best studied is the Evalve MitraClip (Abbott Laboratories, Abbott Park, IL). This system requires a 24F introducer, TEE guidance, and transseptal approach in order to place a clip that will approximate the valve leaflets at the midpoint.[307] This repair technique is based on a type of open repair first described by Ottavio Alfieri, which results in a double oriface MV.[308] Short term outcomes of patients with 3–4+ MR were assessed in the EVEREST prospective multicenter single-arm trial of the MitraClip system. One hundred and seven patients underwent the procedure, 74 percent had immediate improvement of MR, while 64 percent had ≤1+ MR on discharge. Ten patients (9 percent) suffered partial clip detachment, while none had clip embolization. At a mean follow-up of 3.2 years 30 percent of the patients underwent open mitral valve surgery. Kaplan–Meier freedom from death was 95.9, 94.0, and 90.1 percent, and Kaplan–Meier freedom from surgery was 88.5, 83.2, and 76.3 percent at 1, 2, and 3 years, respectively.[309] The EVEREST II study, a multicenter, randomized controlled trial comparing Evalve MitraClip to open surgery demonstrated that the device was significantly less effective at reducing MR than surgery, but the procedure was associated with superior safetly and similar improvements in clinical outcomes. In an associated study the patients that eventually underwent open valve repair were analyzed. Indications for surgery in this group included partial clip detachment ($n = 10$), residual or recurrent MR greater than 2+ ($n = 9$), and other [atrial septal defect ($n = 2$), device malfunction ($n = 1$), and incorrectly diagnosed mitral stenosis ($n = 1$)]. Eighty-seven percent of patients successfully underwent the planned procedure leading the authors to conclude that standard surgical options were preserved in this group of patients.[310] As technology advances and evolves, it is likely indications for percutaneous MV intervention will expand.

## Outcomes and Prognosis

### EARLY RESULTS

Few studies have separately addressed the risks and results of MV surgery for acute MR. Historical series report 30-day mortality rates from 10 to 70 percent,[277,282,311,312] but they do not have significant applicability to contemporary series, and the wide range probably reflects differences in patient selection rather than operative technique. Outcomes have improved, and operative mortality for acute severe MR in most contemporary series (whether limited to PM rupture or inclusive of all types of acute MR) is approximately 20 percent.[313,314] Patients in cardiogenic shock have higher early mortality in all series.[228,278,279,314] Although patient selection may play a role, the 40 percent mortality reported after surgery for acute MR still improves on the 71 percent mortality seen with medical therapy in the SHOCK registry by a wide margin.[313] Early operation in the absence of hemodynamic compromise does not appear to have an effect on operative mortality.[228,279] There is not a clear consensus about the benefits of repair vs replacement in the acute MR population, and large series suggest that the outcomes are probably similar, although many authors continue to recommend replacement in the acute setting.[279,315]

In three large recent reports limited to MV surgery in IMR, operative mortality was 13 percent.[228,279,314] Previous series had a wide spectrum of operative results that ranged from 3.0 to 29.4 percent; this may have been affected by the variable inclusion of patients with chronic non-IMR as well as the heterogeneous population undergoing MR in the setting of coronary artery disease.[205] Similar mortality was observed in the series by Cohn and associates that dealt with patients undergoing concomitant CABG and MVR for IMR.[267] Although multiple studies have demonstrated the

negative impact of concomitant CABG on operative mortality during MV surgery,[314,316–318] this probably reflects the underlying pathology rather than the choice of operative procedure. The large series reported by Grossi and associates[279] and Gillinov and coworkers[228] attempted to control for patient selection in order to compare valve replacement with valve repair. Those authors have initiated an emerging consensus that suggests that valve repair is superior to replacement in this population. Risk factors for early mortality after MV surgery include older age, cardiac dysfunction, complex jet direction (for patients undergoing repair), and severe wall motion abnormalities.[228,279]

### LATE RESULTS

Patients undergoing valve replacement rarely require reoperation for valve failure.[319,320] Although there have been concerns about durability of valve repair for IMR, long-term freedom from repair failure requiring reoperation is excellent: 98 percent at 30 days, 96 percent at 1 year, and 91 percent at 5 years.[228] However, many patients with recurrent MR may not reach reoperation or may not be operative candidates at the time of repair failure. Severe MR may recur in up to 5 percent of patients, and mild-to-moderate MR in 50 percent.[321]

Despite improvements in technique and operative care, only 55 to 60 percent of patients survive 5 years after surgery. In Gillinov's series, among the lowest-risk patients, survival with repair was 58 percent (replacement only, 36 percent), but the highest risk patients had 5-year survival below 50 percent regardless of the procedure performed.[228] Similar results were obtained by Grossi and coworkers.[279] Risk factors for poor outcomes in these groups included poor preoperative cardiac function, previous cardiac surgery, use of suture rather than ring annuloplasty, inferior or lateral wall motion abnormalities, and preoperative atrial fibrillation.[228,279] The poor outcomes probably reflect the impact of large MIs and progressive LV failure on survival and will not be ameliorated by improvements in mitral surgical techniques.

## Summary

There are three forms of IMR: PM rupture, acute MR, and chronic MR. PM rupture requires emergent operative repair, usually with MV replacement, after resection of the ruptured portion. In patients with acute severe MR secondary to ischemia, indications for operation vary between institutions, but emergent revascularization is indicated. When revascularization via thrombolysis or PCI is ineffective, surgical revascularization and MV surgery (usually replacement) are indicated. In patients with chronic MR, MV repair appears to have outcomes equivalent to or better than those of replacement in most populations. Indications for repair include 3+ to 4+ MR in patients needing revascularization. In patients not requiring revascularization, operative decision making is more complex, but in general, symptomatic patients or those with depressed LV function [ejection fraction less than 50 percent or electrostatic discharge (ESD) greater than 50 mm] should be considered for isolated MV procedures. Operative mortality in patients with IMR is approximately 13 percent. Although long-term freedom from reoperation (even with valve repair) exceeds 90 percent at 5 years, survival at 5 years is only 55 to 60 percent. Poor outcomes reflect the impact of large infarctions and extensive coronary disease rather than problems with the mitral surgery.

# VENTRICULAR SEPTAL RUPTURE

## Introduction

First described at autopsy in 1845 by Latham,[322] VSR is a rare but highly lethal complication of MI. The first antemortem diagnosis was not made until 1923,[323] and it would be another 30 years before Cooley and associates[324] performed the first successful repair. Since that time, rapid diagnosis and prompt surgical repair represent the best chance for survival.

Although earlier reports described septal rupture in 1 to 3 percent of cases of MI,[325,326] the advent of reperfusion and aggressive strategies of revascularization have reduced that rate to less than 0.5 percent.[327] However, mortality remains high, and with only 24 percent of medically treated patients (none of them with cardiogenic shock) surviving to 30 days,[328] surgical repair affords an improvement in outcomes, although long-term survivors remain rare.

## Pathophysiology

### PATHOLOGY

VSR occurs after a large transmural infarction when enough necrosis occurs to weaken the septal wall. Infarctions complicated by VSR are larger than those which are not,[329,330] and patients with rupture appear less likely to have diffuse coronary artery disease[328,331,332] (though this has not been found in all reports[333]), to have had previous episodes of angina or MI,[325,332,334–337] and to demonstrate evidence of collateral circulation.[331,334,337] This suggests that large infarctions in myocardial regions that are poorly supplied with collateral perfusion may be at particular risk, but otherwise the reason some hearts rupture and others do not is not clear.

There are two types of VSR: simple and complex (Fig. 31-17). Simple ruptures are discrete lesions with defects at a similar level in both ventricles. The path between the ventricles follows a straight path through the infarcted myocardium. In contrast, complex ruptures have a convoluted dissection path between the ventricles with regions of extensive hemorrhage and may include areas remote from the primary infarction site. Complex morphology occurs more

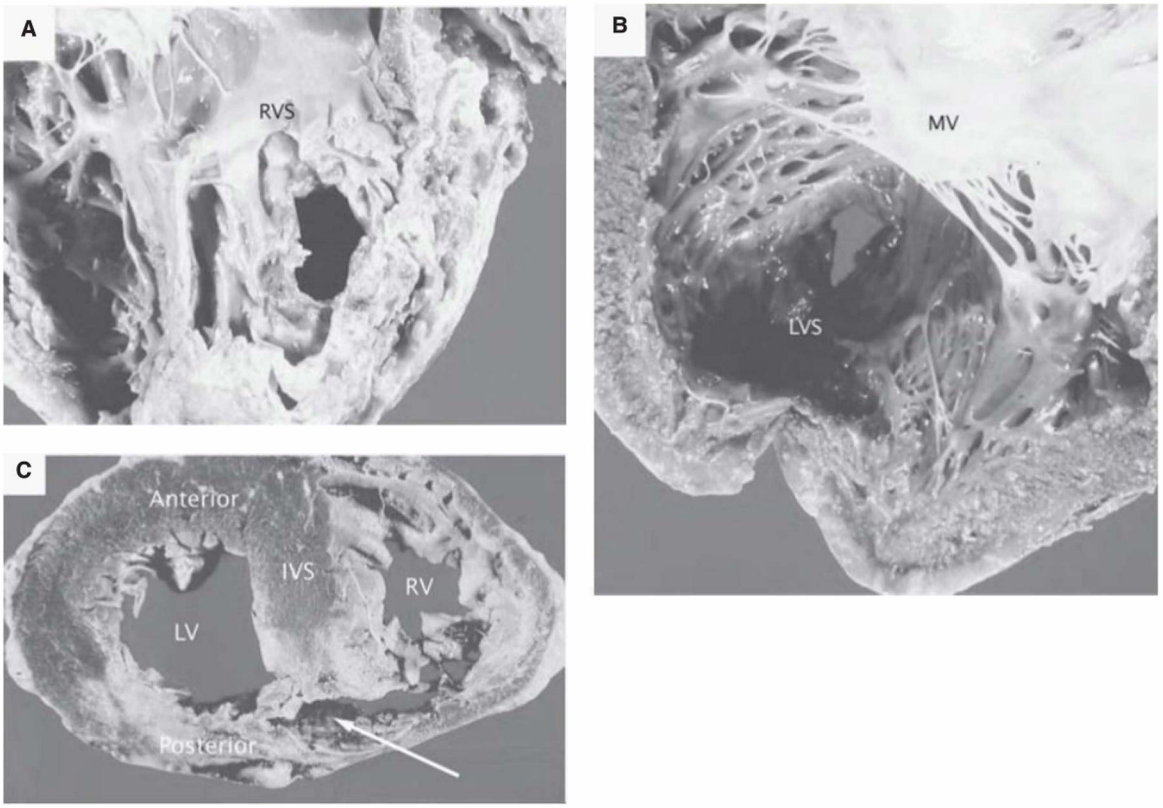

**FIGURE 31-17** Pathologic specimens of ventricular septal rupture. **A** and **B.** Simple ventricular septal rupture with a direct through-and-through connection across the septum. The perforation is at the same level on both sides of the septum. **C.** Complex septal rupture (*arrow*) after infarction of the basal inferior septum and adjacent ventricular wall. LVS, left ventricular aspect of the ventricular septum; RVS, right ventricular aspect of the interventricular septum; MV, mitral valve; IVS, interventricular septum; LV, left ventricle. (From Birnbaum Y, Fishbein MC, Blanche C, Siegel RJ. Ventricular septal rupture after acute myocardial infarction. *N Engl J Med* 2002;347(18):1426–1432.)

commonly with inferior infarcts, whereas anterior infarcts are associated with simple VSR.[333]

Anterior VSR usually occurs after acute occlusion of the LAD coronary artery and most often is located where the septum joins the free wall. Infarcted myocardium occupies a large section of the anterior portion of the septum. Inferior VSRs occur after occlusion of the right coronary artery. They may be located near the base of the heart, abutting the MV annulus, midway between the base and apex, or, less commonly, near the apex. Midseptal defects, usually resulting from occlusion of a large septal perforating artery, are rarer.

The size of the rupture varies considerably, from millimeters to centimeters, and in 5 to 11 percent of cases, multiple defects are present.[338] VSR may occur in combination with other mechanical defects, including PM or ventricular free wall rupture.[339] MR occurs in approximately 33 percent of cases but more often results from LV dysfunction than from PM rupture.[340]

## PATHOPHYSIOLOGY

Interventricular rupture results in a left-to-right shunt of variable magnitude and a significant biventricular hemodynamic load on an already ischemic heart. In most patients, this leads to progressive clinical deterioration, although small ruptures with small shunts may be better tolerated. Initially, the shunt manifests primarily as RV volume overload and increased pulmonary blood flow. Secondary LVvolume overload then results. The diversion of blood flow from the systemic to the pulmonary circulation ultimately leads to a low-output cardiac state; this may be more severe in patients with normally compliant right ventricles.[326] Systemic vasoconstriction in response to peripheral hypotension and hypoperfusion results in a worsening of the left-to-right shunt. A progressive spiral in cardiac function results, leading to worsening myocardial perfusion, increased myocardial workload, infarct extension, and ultimately end-organ hypoperfusion and cardiogenic shock. As the LV fails and systemic pressure declines,

the volume of the shunt ultimately decreases as cardiovascular collapse ensues.

## Clinical Features

Changes in the incidence of VSR after MI with the advent of reperfusion therapies have been associated with a change in the timing of presentation. Historically, most patients presented approximately 5 to 6 days after MI.[341] In the current era, the median time to rupture after MI is less than 24 h.[332] Risk factors for VSR after MI include advanced age, hypertension, and the absence of a history of MI or angina.[325,330,332,334–337,342,343] The influence of gender on the incidence of VSR is not clear. Many surgical series contain a preponderance of men,[344,345] and larger series have documented a higher incidence of rupture among women.[327,332]

The symptoms associated with VSR are those of myocardial ischemia, low cardiac output, and shock, particularly when these symptoms occur after resolution of the initial symptoms. Recurrence of chest pain and shortness of breath are common.[336] A harsh pansystolic murmur heard loudest at the left lower sternal border or a palpable parasternal thrill may be present in up to 50 percent of patients with acute VSR; however, the onset of cardiogenic shock may lead to a decrease in turbulent flow and a loss of the murmur.[328] ECG often demonstrates new ST-segment elevation.[336] The location of the infarct on ECG correlates well with the location of the septal rupture.[346]

## Diagnostic Modalities

In a patient with acute cardiovascular collapse after MI, the differential includes VSR, free wall rupture, and MR (with or without PM rupture) as well as acute ventricular dysfunction (Table 31-7).[339] Because free wall rupture has a very different presentation dominated by the signs of pericardial tamponade, the primary diagnostic dilemna with VSR is differentiating patients with MR from those with VSR; this can be made more difficult by the coexistence of these entities in up to 20 percent of patients.[347–349] Differentiation based on clinical examination is difficult, although clues to the existence of VSR include a palpable thrill that generally is not evident in MR and the lack of the severe pulmonary edema common to MR. However, in low-output states,

**TABLE 31-7: Clinical Characteristics of Ventricular Septal Rupture, Rupture of the Ventricular Free Wall and Papillary Muscle Rupture**

| Characteristic | Ventricular Septal Rupture | Rupture of Ventricular Free Wall | Papillary Muscle Rupture |
|---|---|---|---|
| Incidence | 1–3% without reperfusion therapy, 0.2–0.34% with thrombolytic therapy, 3.9% among patients with cardiogenic shock | 0.8–6.2%; thrombolytic therapy does not reduce risk; primary PTCA seems to reduce risk | About 1% |
| Time course | 3–7 days without reperfusion therapy; median, 24 h with thrombolysis | 1–7 days without reperfusion therapy; mean, 2.7 days with thrombolysis | Median, 1 day (range 1–14 days) |
| Clinical manifestations | Chest pain, shortness of breath | Anginal, pleuritic, or pericardial chest pain, syncope, hypotension, arrhythmias, nausea, restlessness, hypotension, sudden death | Abrupt onset of shortness of breath and pulmonary edema; hypotension |
| Physical findings | Harsh holosystolic murmur, thrill (+), $S_3$, accentuated second heart sound, pulmonary edema, RV and LV failure, cardiogenic shock | Jugulovenous distention (29% of patients), pulsus paradoxus (47%), electromechanical dissociation, cardiogenic schock | A soft murmur in some cases, no thrill, variable signs of RV overload, severe pulmonary edema, cardiogenic shock |
| Echocardiographic findings | Ventricular septal rupture, left-to-right shunt on color flow Doppler echocardiography through the ventricular septum, pattern of RV overload | >5 mm pericardial effusion not visualized in all cases, layered, high-acoustic echoes within the pericardium (blood clot), direct visualization of tear, signs of tamponade | Hypercontractile LV, torn papillary muscle or chordae tendineae, flail leaflet, severe mitral regurgitation on color flow Doppler echocardiography |
| Right heart catherization | Increase in oxygen saturation from RA to RV, large V waves | Ventriculography insensitive, classic signs of tamponade not always present (equalization of diastolic pressures among the chambers) | No increase in oxygen saturation from RA to RV, large V waves, very high pulmonary capillary wedge pressures |

PTCA, percutaneous transluminal coronary angioplasty; RA, right atrium; RV, right ventricle; LV, left ventricle.

From Birnbaum Y, et al. Ventricular septal rupture after acute myocardial infarction. *N Engl J Med* 2002;347(18):1426–1432.

these clues may not allow differentiation between the two complications.

Historically, right heart catheterization was the diagnostic tool of choice for distinguishing these entities.[350] In VSR, RV oxygen saturation is increased, whereas the increase in MR is confined to the pulmonary artery vasculature. However, advances in both transthoracic and TEE have led to their supplanting right heart catherization in the diagnosis of VSR. Doppler echocardiography can identify the site and size of left-to-right shunts through the septal defect accurately, and sensitivity and specificity as high as 100 percent have been reported in the differentiation of VSR from MR (Fig. 31-18).[351,352] In addition, echocardiography can be used to assess the degree of both right and left ventricular impairment in these patients.

LV catheterization with angiography has both advantages and disadvantages. Angiography is time-consuming, and the load of contrast dye may be detrimental to both renal and ventricular function; in patients with significant end-organ hypoperfusion, this is an important concern. However, when concomitant coronary revascularization is being considered, angiography helps delineate coronary anatomy. As many as 60 percent of patients with VSR may have significant disease in coronary arteries other than the one perfusing the affected portion of the septum, and revascularization may improve long-term survival.[353] Therefore, if the patient's condition permits, preoperative coronary angiography should be performed.

## Medical Therapy

Medical therapy consists of both mechanical and pharmacologic support of cardiac function and end-organ perfusion. In most cases, after the diagnosis of VSR, these therapies are merely temporizing measures. They may allow for the performance of further diagnostic procedures (including cardiac catheterization when appropriate) and maintenance of perfusion en route to the operating room, but operation remains the only definitive treatment.

The goals of medical therapy in this setting are (1) maintenance of end-organ perfusion, (2) optimization of coronary perfusion, (3) reduction in myocardial oxygen demand, and (4) reduction in SVR to minimize the left-to-right shunt. In patients without hypotension, vasodilators such as nitroprusside may be useful in reducing SVR; however, they may cause a significant decrease in coronary perfusion as well as end-organ compromise if hypotension occurs.[53] Diuretics may help reduce SVR and preload without similar effects on coronary perfusion. Although inotropic agents may be required to maintain systemic blood flow (and nearly all patients with cardiogenic shock and VSR require them),[332] the increase in systemic pressure may worsen shunting and exacerbate the shift in blood flow from the systemic to the pulmonary circulation. IABP remains the only method that can accomplish all these goals. Counterpulsation decreases LV afterload, which reduces the right-to-left shunt while augmenting cardiac output and end-organ perfusion. Through diastolic augmentation, coronary perfusion is maximized. The advantages of IABP suggest that an IABP should be inserted into all patients with VSR and hemodynamic compromise. Although it cannot treat VSR in the long term, it may provide enough time to perform cardiac catheterization, and it optimizes the patient's hemodynamic status before the induction of anesthesia. IABP improves hemodynamics in all patients with VSR, and those patients tolerate counterpulsation well without loss of the beneficial effect with insertion times longer than 24 h.[354]

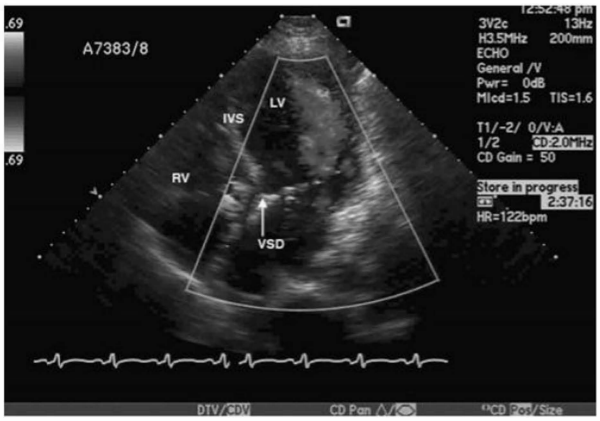

**FIGURE 31-18** Doppler echocardiography demonstrating an ischemic ventricular septal rupture with flow through the ventricular septum during systole. LV, left ventricle; RV, right ventricle; IVS, interventricular septum; VSD, ventricular septal defect.

## Surgical Therapy

### TIMING OF SURGERY

The first successful repairs of VSR were performed in patients more than 1 month after the rupture event.[324–356] It was felt at that time that patients would not tolerate earlier repair both because of their poor hemodynamic status and because it was felt that recently necrosed myocardium would not hold sutures. Those successes, as well as the abrupt acute decompensation and clinical deterioration in other patients, led to the belief that patients with VSR should not be operated on for 1 month after rupture. However, delayed surgery after rupture probably simply selected out patients with smaller defects and relatively preserved hemodynamics whereas patients with more severe disease died during the delay.[357,358] Patients who were not operated on were unlikely to survive the hospital stay, and many patients underwent operative repair only after cardiovascular collapse; 4-week mortality without operation is 80 to 90 percent, and 1-year mortality approaches 100 percent.[327,358,359] More recent data from the SHOCK registry confirm the poor outcomes in critically ill patients with VSR who do not reach operative

repair. The registry followed 55 patients with cardiogenic shock secondary to VSR; 24 were managed medically, and 31 underwent high-risk surgery. Overall survival was 28.6 percent among those treated surgically but only 4.2 percent among those treated medically.[332] Because of these dismal outcomes, attempts were made to operate earlier, and in 1977, Daggett and associates reported increased survival in 43 patients operated on early for VSR.[357] Early operation also may decrease the risk of subsequent free wall rupture, which often is preceded by VSR.[336] Since that time, other authors have confirmed the relative survival advantage of early operation in these patients, and operation within 24 to 48 h has become the standard.[360]

Patients presenting after VSR can be grouped broadly into four groups on the basis of hemodynamic status at the time of diagnosis. The first group consists of the few patients who remain hemodynamically stable and in whom a small left-to-right shunt is well tolerated without hemodynamic support or end-organ compromise. These patients may be managed medically until it is convenient to perform the repair, but operative repair should be performed before hospital discharge. The second group consists of patients in cardiogenic shock. This is the largest group of patients with VSR.[327,361] Another large group of patients occupies an intermediate position between those in the first two groups; these patients require operation within 12 to 24 h. Their clinical stability on initial presentation should not lead to medical management or an attempt to delay operation; further deterioration will result, and the patient will require emergent and risky surgical repair. The final group consists of patients who present after the onset of end-organ damage or sepsis. These patients are not likely to survive surgery, and there are case reports of survival using long-term IABP support until they can tolerate operative repair.[362]

## OPERATIVE TECHNIQUE

***General Considerations.*** After median sternotomy, CPB is initiated swiftly with bicaval cannulation. LV venting is not required, as the LV should vent spontaneously via the septal defect and insertion of a vent may dislodge any mural thrombus present in the LV. For the same reason, manipulation of the heart before clamping should be minimized. As with other patients undergoing cardiac operations in proximity to myocardial ischemia, both retrograde and antegrade cardioplegia should be used. Distal coronary anastomoses should be performed before ventriculotomy; this both maximizes myocardial protection and minimizes manipulation of the fragile ventriculotomy repair.

The surgeon often is challenged by the weak and friable myocardium in both the septum and the infarcted regions of the ventricular free wall. These regions have a tendency to weaken, fail, and lead to a residual defect. The use of a generous pericardial patch is important in reducing tension and decreasing the risk of a residual or recurrent septal defect. The closure of the left ventriculotomy, particularly when large free wall infarcts are present, must be performed with large 1-cm bites of tissue and extensive use of felt buttressing to decrease the risk of postoperative free wall rupture.

***Surgical Approach to Interventricular Septal Rupture.*** The first repair by Cooley and associates[324] involved a right ventriculotomy for access to the interventricular septum, as was used in the approach to congenital VSR. Unfortunately, this approach has multiple disadvantages: (1) Exposure of the defect is not optimal, (2) damage occurs to the normal myocardium of the right ventricle, (3) collateral blood flow from the right coronary circulation is cut off, and (4) it fails to address the portion of infarcted LV wall that results in paradoxic bulging during ventricular systole. With these weaknesses in mind, Heimbecker and coworkers[363] developed the technique of left ventriculotomy; this allows simultaneous repair of the septal defect along with infarctectomy and aneurysmectomy. This has become the standard surgical approach to most VSR repairs.

***Apical Septal Rupture.*** The technique of apical rupture repair is perhaps the most simple, but apical VSRs are rare. Daggett and coworkers first described the technique of apical amputation in 1970.[364] An incision is made through the necrotic LV apex and through the septum and the RV free wall. This results in amputation of the apex of the heart. The repair is completed by approximating the ventricular free walls to the septum, using Teflon felt strips and horizontal mattress sutures (Fig. 31-19).

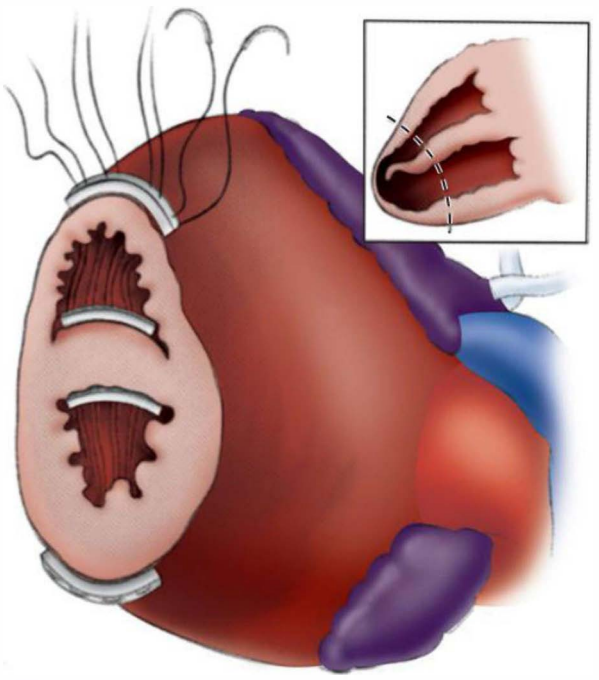

**FIGURE 31-19** Amputation of an apical septal rupture with biventricular closure using pledgeted sutures. (Adapted from Fig. 22.11 in Buxton BF, Frazier OH, Westaby S (eds). *Ischemic Heart Disease Surgical Management*. Philadelphia: Mosby, 1999.)

***Anterior Septal Rupture.*** The initial approach to anterior septal rupture is via a transinfarct left ventriculotomy with infarct excision. Some small anterior defects may be closed without a prosthetic patch by approximating the free anterior edge of the septum to the RV free wall with mattress sutures of Tevdek over strips of felt. However, most defects require the insertion of a patch to obtain a tension-free repair.

The classical technique involves debridement of the VSR and if necessary slight enlargement of the defect. This permits the placement of horizontal mattress sutures from the RV side of the defect through a thick felt patch and then through the septum. The sutures then are passed through the patch approximately 8 mm from the edge and tied into place. The patch is brought out through the ventriculotomy incision, and the incision is closed. Wide bites of viable LV wall are taken, and the closure is buttressed with large felt patches. In this technique, if there is not sufficient anterior septum to anchor the anterior portion of the patch, horizontal mattress sutures may be passed from the epicardial to the endocardial surface of the right ventricle to complete the repair.

As surgical repair has occurred earlier, the strength of the myocardium holding the patch sutures has become a significant issue. Although sutures should be placed into viable myocardium, in the first 24 h after infarct it may be difficult to differentiate viable from nonviable regions. The addition of tissue adhesives to repair techniques adds strength and theoretically reduces the risk of postoperative dehiscence of the septal patch. Seguin and associates described the first use of fibrin sealant in reinforcing patch closure of VSR in three patients.[365] Refinements in technique and biological adhesive have led some authors to advocate the repair of VSR with a pericardial patch and gelatin–resorcinol–formaldehyde (GRF) biological glue.[366] In this technique, placement of the patch is similar to that in the classic approach. However, the sutures anchoring the patch to the septum are placed at a wider radius to ensure attachment to viable myocardium. This suture is a running suture without pledgets. GRF glue is applied over the septal side of the pericardial patch through to the ventriculotomy closure. Excellent results have been obtained with this technique, and successful repair of cardiac rupture without the use of sutures has been reported.[367–370] There has been theoretical concern that the formaldehyde might inhibit ventricular remodeling and growth of fibrous tissue into the patch area. Although autopsy studies have not demonstrated that problem,[368] the next generation of glues promises to alleviate this theoretical concern.

***Posterior Septal Rupture.*** The repair of inferoposterior septal defects is made more difficult by exposure of the posterior of the heart as well as the proximity of both the PDA and, on the endocardial surface, the posteromedial PM. After cross-clamping, the heart is retracted out of the cardiac well and the posterior surface is exposed. A left ventriculotomy is made through the infarct approximately 1 cm lateral to the PDA, with care taken to leave the PMs undamaged. The patch then is cut and secured with running 4-0 monofilament sutures. As with anterior defects, the patch then may be brought out through the ventriculotomy and secured.

Inferior infarctions with significant LV free wall enlargement require additional techniques. In these cases the infarcted ventricular wall often is thinned out. Use of this weakened myocardium for closure increases the risk of rupture. To strengthen the repair, the ventriculotomy is closed with a Dacron free wall patch backed with pericardium. The patch is secured to the ventricular wall with interposed felt strips on both the epicardial and the endocardial surfaces to strengthen the attachment points.

***Repair by Infarct Exclusion.*** Athough emergent operative treatment for VSR provided an improvement over the nonoperative management of these patients, mortality rates remained high, exceeding 30 percent in nearly all large series.[326,358,371] The recognition of the importance of LV geometry to appropriate LV function led to a desire to avoid resection of infarcted myocardium as much as possible. This is especially important because patients with higher shunt flow, and therefore better ventricular function, have improved survival rates after VSR repair.[371] David and colleagues[372] and others[373–376] developed the technique of infarct exclusion to exclude the defect and infarcted myocardium from the high-pressure LV system without resection of regions of myocardium, thus preserving normal LV function as much as possible.

As with the techniques discussed above, bicaval cannulation is performed and antegrade and retrograde cardioplegia is given. Occluded coronaries are bypassed before the ventriculotomy is begun. For anterior septal defects, an incision is made in the apex of the LV and extended toward the base of the heart approximately 1 cm lateral to the LAD coronary artery through the ventriculotomy. Stay sutures are placed into the ventricular wall to provide exposure, and the endocardial surface is examined. A glutaraldehyde-fixed pericardial patch is cut to fit over the entire extent of infarcted myocardium (in most patients this is approximately $4 \times 6$ cm[372]). Starting at the lowest and most proximal part of the septum, the patch is secured to healthy myocardium with 3-0 polypropylene sutures in a running fashion (Fig. 31-20). Another suture starting at the same point secures the opposite side of the patch to the noninfarcted portions of the anterolateral LV wall. When the two suture lines meet, the sutures are tied to each other, and the infarcted myocardium becomes excluded from the left ventricle. Closure of the ventriculotomy then proceeds with a buttressed repair of horizontal mattress stitches.

If the infarction extends into the base of the anterior PM, it may not be possible to exclude the infarct completely from the LV cavity. In this case, the suture line is brought through the myocardium and buttressed on the epicardial surface with Teflon or pericardial strips. Other authors recommend passing all sutures through to the epicardial surface; in the region of the defect, the suture is passed through the septum and then through the RV free wall to allow buttressing at the epicardial surface.[373]

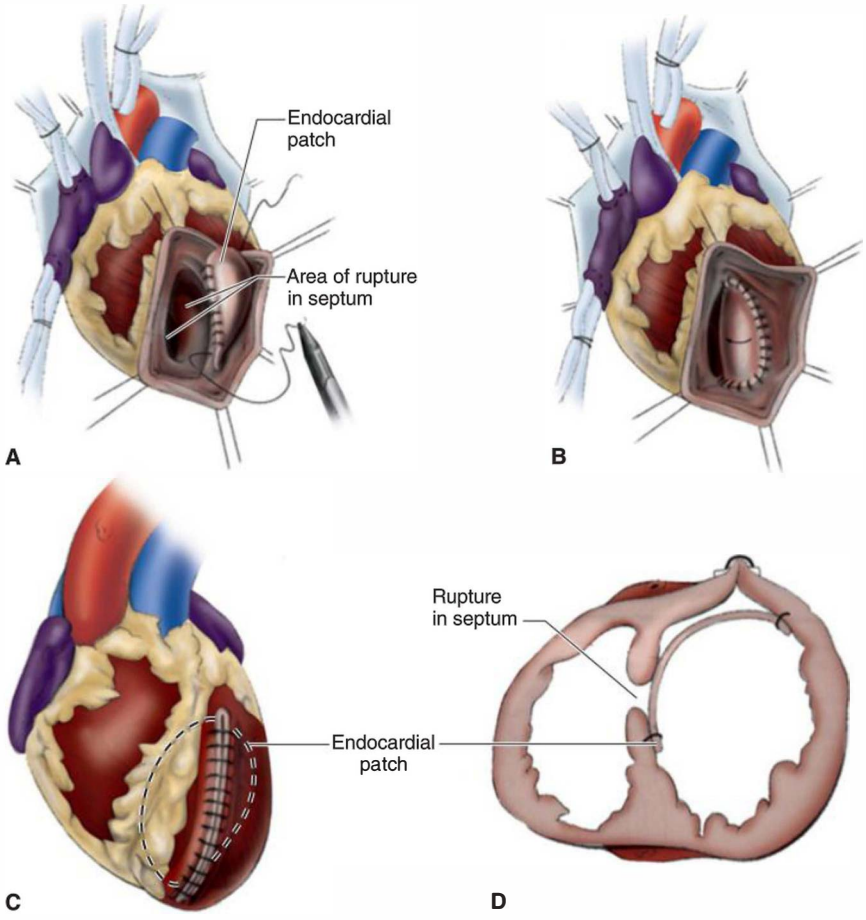

**FIGURE 31-20** Repair of an anterior septal rupture with an endocardial patch and infarct exclusion. An oval pericardial patch is sutured to the septum and lateral wall to exclude the infarcted muscle from the left ventricular cavity. (Modified from David TE, Dale L, Sun Z. Postinfarction ventricular septal rupture: repair by endocardial patch with infarct exclusion. *J Thorac Cardiovasc Surg* 1995;110(5):1315–1322.)

Repair of a posterior VSR is performed with a similar goal—exclusion of the infarct region from the LV cavity—although as with patch repairs, the proximity of the PMs increases the difficulty of these repairs. The initial incision is made through the posterior wall of the left ventricle, 1 to 2 cm lateral to the PDA, and extended to within 1 cm of the mitral annulus. The incision also is extended toward the apex and the base of the posterior PM. Stay sutures are secured to the ventricular wall; in particular, a suture securing the apex of the heart in the direction of the upper part of the sternotomy facilitates adequate exposure.[377]

The posterior patch is cut in the shape of a triangle to encompass all of the infarct (usually approximately 4 × 7 cm). The base of this triangular patch is secured to the fibrous annulus of the MV, beginning at the middle of the posterior leaflet and extending toward the medial commissure until healthy septal myocardium is reached. The patch is trimmed as needed and sutured to healthy endocardium, using a continuous 3-0 polypropylene suture extending toward the apex of the heart. Finally, the medial side of the patch is sutured to the posterior wall of the left ventricle, using interrupted full-thickness bites buttressed on the epicardial side with a Teflon strip. This excludes the infarct zone from the LV cavity, and the ventriculotomy is closed with buttressed interrupted sutures.

A recent modification of infarct-exclusion included the use of a double-patch technique in which the VSR is closed with a small pericardial patch before insertion of the infarct-excluding patch.[367,378] The inter-"patch" space then is filled with glue. The theoretical advantages of this technique include a more physiologic reconstruction of the interventricular septum, avoidance of contact between tissue adhesive and the systemic circulation, and decreased tension on the infarct-excluding suture lines.[367] Whether these benefits are worth the extra time required for placement remains to be established.

### CONCOMITANT CORONARY ARTERY BYPASS

Reports of coronary artery bypass during repair of VSR describe conflicting results. The disadvantages of concomitant CABG include risk of preoperative left heart catheterization in hemodynamically compromised patients and the prolonged operative and CPB times. Although some authors have reported decompensation among approximately 5 percent of patients undergoing angiography,[379] more recent reports suggest that preoperative angiography is not associated with adverse changes in hemodynamics or clinical status.[361,380] Other authors question the value of angiography in the setting of VSR. Although in many series most patients have single-vessel disease,[379,381,382] this is not universally true,[361] and even when it is, as many as 45 percent of patients have multivessel disease. Even patients with anterior infarction and without a previous history of ischemic heart disease do not *invariably* have single-vessel disease.[361] Thus, routine angiography in this population appears to carry little additional risk and may provide useful information; in addition, it allows guided placement of an IABP for hemodynamic stabilization.

Independent of the risk of angiography, some authors question the utility of coronary revascularization in this population. The data in this respect are not clear; however, although many studies have not shown a survival advantage among patients undergoing concomitant CABG, they also have not shown a detrimental effect of CABG despite longer operative and bypass times.[381,383] Other studies have shown improvements in middle- and long-term survival with concomitant CABG.[361,384] Data do not demonstrate a definitive survival advantage, but no disadvantage to preoperative angiography and concomitant CABG has been demonstrated. The authors recommend routine angiography and bypass of severe proximal stenoses in these patients.

### PERCUTANEOUS CLOSURE OF SEPTAL RUPTURE

Because of the poor clinical status of patients with VSR, percutaneous closure of the defect offers notable advantages in that it does not require operation and CPB and does not have the potential for dehiscence of the ventriculotomy closure that results in rupture. Several case reports have described the successful use of the Amplatzer ventricular septal closure device in residual defects after surgical repair.[385–390] In addition, a recent case report demonstrated successful intraoperative deployment of the device under direct vision through a right atriotomy providing primary repair of VSR.[391] The use of percutaneous devices in the acute postinfarct period has been less successful, and all survivors who had not had previous surgeries had transcatheter closure remote from their infarcts.[390,3392] It is likely that the soft, friable edges of the defect do not provide an adequate anchor for the device, leading to residual shunting and hemodynamic deterioration.[393] Further refinements in techniques are necessary before percutaneous closure of VSR becomes routine, although its use in closure of residual postsurgical defects appears warranted.

### VENTRICULAR ASSIST DEVICES

The use of VADs for hemodynamic support in these patients as a bridge to transplantation is challenging. It may be difficult to secure the cannulas to the postischemic necrotic heart. There are case reports of VAD placement as early as 7 days after MI for postrepair residual defects.[394] However, the use of VADs in the provision of hemodynamic support for patients with an unrepaired VSR has been less successful. One concern particular to patients with VSR is an increase in right-to-left shunting that results in hypoxia and cerebral hypoperfusion.[395] VADs also may be helpful as a bridge to recovery in patients who cannot be weaned from CPB. Biventricular support may be required both in patients with RV infarction and in those with residual defect (to prevent an increase in right-to-left shunting), and also may be used as a bridge to surgical repair.[396]

## Outcomes and Prognosis

### POSTOPERATIVE MORTALITY

Several large series have examined outcomes in surgery for VSR. In-hospital and 30-day mortality rates are between 20 and 50 percent even in recent series.[326,345,358,361,371,372,380,381,383,397–401] Preoperative characteristics significantly affect the risk of negative outcomes after surgery. The most important predictor of postoperative survival remains preoperative hemodynamic status.[361,372,380,381,400,401] Although measured in a variety of ways (including the presence of cardiogenic shock,[372,381,400,401] the need for inotropic support,[361,380] and the presence of renal failure[372]), increased mortality invariably is seen in patients with poor preoperative cardiac function. Other variables that affect early postoperative survival include posterior infarct location,[398,400] total occlusion of the infarct-related artery,[361] and RV infarction[380] or failure.[372] The poor prognosis of patients with posterior infarcts and VSRs has been attributed to the coexistence of MR in those patients, the increased technical difficulty of repair, and the associated RV infarction.[357,383,402,403] Older age, particularly in patients with poor preoperative clinical status, predicts poor outcomes in some studies,[338,357] but this has been a variable finding.

### IMPACT OF OPERATIVE TECHNIQUE

Mortality rates vary widely among reported series. Other groups have had difficulty replicating the outcomes of the Toronto group with infarct-exclusion. In their experience, no deaths occurred in patients without cardiogenic shock, and overall mortality was only 14 percent.[372] Unfortunately, others have had mortality rates ranging from 30 to 60 percent with similar repairs.[338,404] Similarly, the publication by Skillington before the development of infarct-exclusion reported an

overall early mortality rate of only 20.8 percent (mortality in the 2 years immediately before the report had declined to 11.1 percent)[405]; other groups using similar techniques have been unable to duplicate those excellent results.

In light of the small samples in even the largest retrospective studies, changes in practice over time that make any single series unlikely to contain a single operative repair, a wide variety in referral patterns, differences in criteria for operative candidates, and the timing of operation, comparison between series is of little value. These rather than other factors probably explain differences in outcomes even when similar repairs are used.

### CAUSES OF EARLY MORTALITY

In most series, approximately 5 to 10 percent of patients cannot be weaned from cardiopulmonary support in the operating room.[372,381,398,401] Progressive cardiac failure with a low-output state is the most common cause of postoperative death (50 percent of early mortality), and some degree of failure is present in nearly all patients during the postoperative period.[345,380,381,398] Other causes of death include postoperative free wall rupture, recurrent VSR, severe MR, bleeding, sepsis, cardiac arrest, respiratory failure, and multiple organ system failure (each accounts for 5–10 percent of mortality, depending on the series).[380,381,398,401,406] The type of repair performed does not appear to affect the relative frequencies of these causes of postoperative mortality.

### OTHER COMPLICATIONS

In most series, recurrence of the VSR occurs in approximately 20 to 30 percent of patients,[345,361,381,401] although the Toronto series of infarct-exclusion contains only a single recurrence with a small residual shunt in 44 cases.[372] The range of recurrence depends on the modality used to detect it. Close echocardiographic follow-up may detect recurrence in nearly 50 percent of patients, but most of these events are not clinically significant and may not influence survival.[381] Patients with small residual defects who are hemodynamically stable may be managed conservatively. In the large series reported by Deja and associates, 14 patients out of the 44 with echocardiographically detected shunts required reoperation.[381] Mortality in patients with clinically significant recurrence approaches 10 percent.[381,405] The double-patch technique has been reported to decrease the recurrence rate in some series,[380] but as with mortality, comparisons between series have little value and further experience with this technique is required. As was noted above, some patients may benefit from percutaneous closure of recurrent or residual defects.[385–390] MR occurs in approximately 2 percent of patients.[381] Other complications are those common to all emergent cardiac surgery, including sternal dehiscence (2 percent), reoperation for bleeding (6 percent), renal failure requiring hemodialysis (25 percent), arrhythmias requiring temporary (27 percent) or permanent pacemakers (1 percent), and stroke (5 percent).[381]

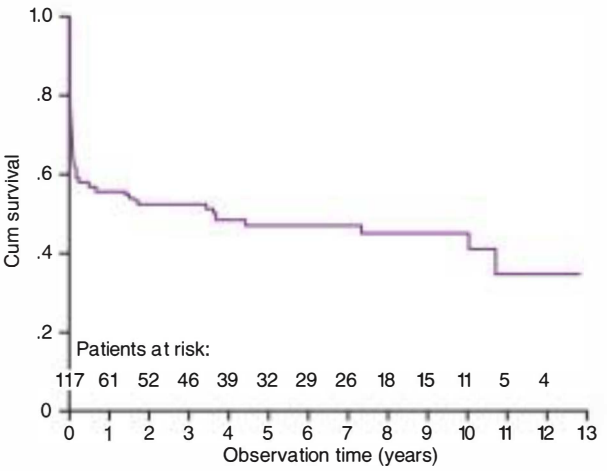

**FIGURE 31-21** Kaplan-Meier survival curve illustrating long-term survival after surgical treatment of ventricular septal rupture. (From Deja MA, Szostek J, Widenka K, et al. Postinfarction ventricular septal defect—can we do better? *Eur J Cardiothorac Surg* 2000;18(2):194–201.)

### LATE RESULTS

Although operative mortality and 30-day mortality are high, hospital survivors have excellent long-term outcomes, especially when their baseline medical status is accounted for (Fig. 31-21[381]). The overall 5-year survival is approximately 50 to 60 percent in recent series.[361,380,381] However, among hospital survivors, 2-, 5-, and 8-year survival of 85, 63, and 61 percent has been reported.[380] Functional status is also impressive: The majority of long-term survivors (70–95 percent) are in NYHA class I or II.[372,380] Late results of earlier repairs are equally striking: Davies and coworkers reported 37 percent survival at 14 years with 82 percent of the survivors in NYHA class I or II.[407]

## Summary

VSR occurs in the week after a large MI that results in a necrotic and weakened portion of the ventricular septum. The patients at highest risk are those who angiographically have single-vessel coronary disease without significant collateralization. Clinically, patients present with recurrence of chest pain, and a new harsh pansystolic murmur may be audible. Medical therapy should be used to stabilize the patient and allow for the performance of a diagnostic workup that includes an echocardiogram. Placement of an IABP improves outcomes through reduction in afterload and improvement in shunt dynamics. Although some patients with small, well-tolerated shunts may be managed conservatively, most patients should undergo urgent operative repair. Multiple repairs have been advocated; postoperative mortality ranges from 20 to 50 percent, and comparisons between repairs have not been useful.

# VENTRICULAR FREE WALL RUPTURE

## Introduction

William Harvey first described ventricular free wall rupture (VFWR) in 1647. Subsequent authors, including Morgagni,[408] Malmsten and Duben,[409] Winsor,[410] Steven,[411] and Krumbhaar and Crowell,[412] further refined the understanding of cardiac rupture, including its relation to coronary occlusive disease, weakening of the myocardium, and recent MI. Despite this early description, the first successful operation was not performed until 1970. In that year, Hatcher and colleagues[413] reported successful repair of a right VFWR; this was followed shortly by successful LV repairs reported by FitzGibbon and associates[414] and Montegut.[415] However, despite improvements in cardiac care, survival after VFWR remains dismal. Although an uncommon complication of MI, it is the second leading cause of in-hospital death after cardiogenic shock.[416,417]

## Pathophysiology

Left VFWR commonly occurs on the anterior or lateral wall of the ventricle at the midpapillary level.[418,419] The endocardial tear is within 1 cm of the base of one of the PMs in 80 percent of cases.[418] Increased mechanical stress in this location probably results from the countering forces of systolic contraction and PM stretch. Rupture usually occurs at the boundary between viable and necrotic myocardium.[419] Most of these patients have multivessel coronary artery disease with complete occlusion or inadequate revascularization of a major coronary vessel.[420] Collateral circulation is usually absent.

Pathologically, Perdigao and associates[421] described four types of rupture:

- Type I: almost direct trajectory without extensive dissection or bloody infiltration of the myocardium
- Type II: multicanalicular trajectory and widespread myocardial dissection and bloody infiltration
- Type III: orifice of rupture protected by intraventricular thrombus or pericardial adhesions
- Type IV: incomplete epicardial, endocardial, or intramyocardial rupture in which the trajectory does not penetrate all layers.

However, the division by Becker and van Mantgem[422] of rupture into three types may be more useful clinically:

- Type I: an abrupt slitlike tear
- Type II: erosion of the infarcted myocardium at the border with viable muscle tissue
- Type III: early aneurysm formation.

These types correspond with the clinical division of ventricular rupture into acute, subacute, or chronic with pseudoaneurysm formation. Acute rupture occurs with sudden massive hemorrhage into the pericardial space and leads to circulatory collapse and death, often within minutes. Subacute rupture, a term first used by O'Rourke,[423] occurs after a smaller tear in the myocardium that may be sealed temporarily with thrombus or adhesions (Perdigao type III). Finally, chronic rupture occurs when blood leaks slowly from the ventricle. In this case, pericardial adhesions form and contain the rupture, resulting in a false aneurysm. The different time courses of these entitities may be affected by infarction location, as fatal cardiac ruptures tend to occur in the anterior and lateral walls, whereas pseudoaneurysm formation is more likely in the inferoposterior walls.[424] The pathogenesis of VFWR is not completely understood. However, increasing knowledge about myocardial repair after infarction provides some insights. After infarction, remodeling begins initially with leukocyte infiltration and clearance of necrotic debris; this leads to a process termed infarct expansion. Clearance of necrotic debris leads to regional thinning and dilatation of the infarcted region of myocardium.[425] Thinning leads to a reduction in the number of myocytes crossing the infarct zone and a corresponding decrease in the tensile strength of the ventricular wall. Dilatation causes increased wall tension (Laplace effect). Thus, infarct expansion results in a period of myocardial weakness (usually 1–4 days post-MI) when the myocardium becomes particularly susceptible to rupture. The importance of remodeling to the pathogenesis of rupture is demonstrated by reduced rupture rates in animal models with inhibition of the plasminogen/matric metalloproteinase system that is responsible for ventricular remodeling.[426,427] This period of weakness may be required for eventual scar tissue formation, as these mice also have poor long-term angiogenesis and scar formation in the infarct region.[426,427]

## Clinical Features

### ACUTE AND SUBACUTE RUPTURE

The incidence of VFWR peaks during the first week after MI. Autopsy studies suggest that 80 percent of ruptures occur within 7 days of MI,[419] and most acute rupture events occur within 48 h of admission.[428] In large retrospective studies, acute VFWR resulted in death a median of approximately 3 days after the onset of symptoms of MI.[416] Risk factors for VFWR include older age (usually more than 60 years),[419,429] female sex,[342,419,429–432] a history of systemic hypertension[419] without LV hypertrophy[419] or sustained hypertension during admission,[342] the presence of a pericardial rub or pericardial effusion,[429,433] sustained chest pain,[342,431] and the absence of previous MI or angina.[419,431]

The overall incidence after MI varies in reported series, as many patients are unlikely to be identified in clinical series because of prehospital death. In autopsy series, as many as 30 percent of MIs may be accompanied by VFWR.[430] In contrast, much lower rates (1–4 percent) are reported among patients surviving to hospital admission for MI.[342,413,417,431,434–437] However, even in these series, it accounts for 6 to 17 percent of in-hospital mortality.[413,431]

**TABLE 31-8: Sensitivity, Specificity, and Positive Predictive Value of Different Variables Used Alone or in Combination for Diagnosing a Postinfarction Ventricular Free Wall Rupture**

| | Sensitivity (%) | Specificity (%) | Positive Predictive Value (%) |
|---|---|---|---|
| Infarct site | | | |
| Anterior | 25 | 70 | 3.9 |
| Inferior | 68 | 54 | 6.7 |
| Lateral | 7.1 | 90 | 3.3 |
| Prior myocardial infarction | 3.5 | 75 | 0.6 |
| Bundle branch block | 32 | 74 | 5.7 |
| Pulsus paradoxus | 46 | 99 | 72 |
| ST–T-wave deviations | 32 | 85 | 10 |
| Syncope | 64 | 91 | 26 |
| Hemodynamic signs of cardiac tamponade ($CT_H$)[a] | 85 | 99 | 0.9 |
| Pericardial effusion (PE) | 100 | 77 | 17 |
| Intrapericardial echoes (IE)[b] | 93 | 99 | 81 |
| Echocardiographic signs of cardiac tamponade ($CT_E$)[c] | 93 | 99 | 93 |
| Combinations of signs | | | |
| Hemopericardium (Hp)[d] | 21 | 99 | 85 |
| PE + type I IE | 7.1 | 99 | 28 |
| Syncope or shock + PE + type II IE + $CT_{E+H}$ | 53 | 100 | 100 |
| Syncope or shock + PE + type I IE + $CT_{E+H}$ | 32 | 100 | 100 |
| Syncope or shock + PE + Hp + $CT_{E+H}$ | 7.1 | 100 | 100 |

$CT_H$, hemodynamic evidence of cardiac tamponade; $CT_E$, echocardiographic evidence of cardiac tamponade; IE, intrapericardial echoes; Hp, hemopericardium; $CT_{E+H}$, echocardiographic and hemodynamic evidence of cardiac tamponade; PE, pericardial effusion.

[a]Hemodynamic signs of cardiac tamponade were the presence of an increase in right atrial pressure and characteristic profile of right atrial pressure waveform (depressed *x* descent and blunted *y* descent).

[b]Intrapericardial echoes could be of two types: type I, a wide, thick undulating band overlying the heart suspended in a moderate to large pericardial effusion, and type II, a massive, homogeneous, and immobile structure impinging on adjacent cardiac chambers.

[c]Echocardiographic evidence of cardiac tamponade was present when right atrial diastolic and/or right ventricular early diastolic collapse was associated with either or both of the following findings: Doppler ultrasound findings of exaggerated tricuspid and pulmonic flow velocities and reduction of peak mitral flow velocity with the onset of inspiration and the opposite changes after the onset of expiration or inferior vena caval plethora with blunted respiratory variation.

[d]Pericardial fluid with hematocrit <25.

Acute rupture is characterized by the sudden onset of chest pain with rapid cardiovascular collapse and pulseless electrical activity caused by pericardial tamponade. These are accompanied by severe jugular venous distention with cyanosis. Death nearly invariably occurs within minutes.[438]

The distinction between these patients and those with subacute rupture has not been defined clearly, but in general, patients with subacute rupture are those in whom pericardial effusion and hypotension of variable severity are not accompanied by pulseless electrical activity and cardiac arrest.[423,439] This subacute form of VFWR occurs in approximately 30 percent of in-patient ruptures,[431,440,441] and early recognition may allow operative repair and increase survival. In this group, the gradual onset of symptoms of pericardial tamponade may be appreciated before the onset of cardiovascular collapse; however, marked jugular venous distention and pulsus paradoxus have been found in only approximately 30 percent[442] and 50 percent[439,443] of patients, respectively. A variety of other signs and symptoms may be present in these patients: arrhythmias (including transient pulseless electrical activity, bradycardias, tachycardias and ventricular fibrillation, syncope, hypotension, shock, and chest pain, which may be transient, prolonged, or recurrent.[423,439,442–446] The sensitivity and specificity of these signs vary (Table 31-8[443]). Particularly in diabetic patients, VFWR may present with sudden collapse from pericardial tamponade even in the absence of antecedent chest pain.[447] Sudden onset of cardiogenic shock in the post-MI period should prompt rapid echocardiographic evaluation to differentiate infarct extension from the various mechanical causes: MR, VSR, and VFWR. Especially in cases of right heart failure or when there are signs and symptoms of pericardial tamponade, rapid diagnostic pericardiocentesis may be indicated.

## CHRONIC RUPTURE WITH PSEUDOANEURYSM

Chronic VFWR with false aneurysm formation is a rare entity that usually develops within 3 months of MI.[448] Traditionally, this was thought to carry a high rupture risk, and immediate operative therapy was recommended.[449–451] However, in a review of 52 patients, Yeo and associates found no deaths caused by cardiac rupture in the 6 patients with post-MI pseudoaneurysm who were managed medically.[424] In another series, 1-year mortality among nine patients who were managed medically was only 22 percent and no patients had rupture of the pseudoaneurysm.[452] Similar results were

obtained in a review by Natarajan and colleagues of the 66 cases reported in the literature.[453] Unfortunately, because of its rarity, the natural history of chronic VFWR with pseudoaneurysm formation has not been defined clearly; the increasing use of echocardiography after MI may allow for the earlier diagnosis of more patients with this disease and allow for better evaluation of the need for operative therapy.

### IMPACT OF REPERFUSION THERAPY

Reperfusion, whether spontaneous or induced, reduces infarct expansion and decreases infarct size.[272,281,454,455] This would be expected to reduce the incidence of VFWR; however, in the case of thrombolysis, there has been concern that the transformation of bland infarcts into hemorrhagic infarcts may increase the risk of rupture.[456–458] In a meta-analysis of four studies, Honan and associates demonstrated a reduction in the risk of rupture when thrombolysis occurred within 7 h but an increased risk after late thrombolysis (after 17 h).[459] Becker and colleagues studied 5,711 patients, and although patients who did have a rupture incurred it earlier (between 6 and 12 h), overall there was no difference in the incidence of rupture when thrombolysis occurred between 6 and 24 h.[417] Thus, early thrombolysis is thought to have a beneficial effect by limiting infarct size and related necrosis and minimizing regions of transmurality.

In contrast, outcomes after percutaneous revascularization have been uniformly positive.[417,460,461] Comparing 762 patients undergoing angioplasty with 613 receiving thrombolysis, Moreno and associates showed a significant reduction in the incidence of cardiac rupture (odds ratio 0.46, 95 percent CI 0.22–0.96).[462] Importantly, increasing time to reperfusion is an independent risk factor for cardiac rupture, reinforcing the importance of timely delivery to the catheterization laboratory.[438] The superiority of percutaneous interventions probably results from improved perfusion without the hemorrhagic or fibrinolytic side effects of thrombolysis.[463]

## Diagnostic Modalities

A high index of suspicion in cases of arrhythmias before cardiogenic shock or the sudden onset of shock or severe chest pain is essential to initiating the diagnostic workup of and initial therapy for VFWR.

### ELECTROCARDIOGRAPHY, CLINICAL EVALUATION, AND RIGHT HEART CATHETERIZATION

Oliva and associates evaluated 70 patients with cardiac rupture and found that patients with rupture were more likely to have persistent, progressive, or recurrent ST elevation (61 percent) than were those with MI without rupture (22 percent, $p \leq 0.002$).[464] Failure of the T wave to invert or reversal of an inverted T wave was also more common among the group with rupture (94 vs 34 percent, $p \leq 0.02$).[464] Unfortunately, because rupture is a rare event, the positive predictive value of these ECG signs was only 58 and 66 percent, respectively.[464] The best predictors of rupture were clinical symptoms such as pericarditis, repetitive emesis, and restlessness or agitation; when two or more symptoms were present, the positive predictive value for rupture was 95 percent.[464] Other criteria for predicting rupture have been proposed: tachycardia greater than 100 beats/min with ST-segment elevation equal to or greater than 0.1 mV in lead $V_5$ (for inferior MI) or lead II (for anterior MI),[465] generalized ST-segment elevation (odds ratio for rupture 9.2),[325] and ST elevation in aVL (odds ratio for rupture 5.4).[466] Unfortunately, because of the relative rarity of cardiac rupture, the positive predictive value of all these criteria tends to be minimal.

Classically, the pericardial tamponade of VFWR should lead to equalization of pressures across the cardiac chambers. Pulmonary artery catheter pressures usually demonstrate evidence of right heart failure: elevated right atrial pressures, the possibility of equalization of right atrial and PCWPs (although pericardial clot may prevent the expected equalization of pressures[467]), and alterations in the right atrial pressure waveform (deep *x* descent and blunted *y* descent).[463] Any of these changes should prompt rapid echocardiography to rule out pericardial tamponade and rupture.

### ECHOCARDIOGRAPHY

Echocardiography is the diagnostic study of choice in patients with suspected VFWR. It is noninvasive, safe, easy to perform even at the bedside, and widely available. However, it does have limitations. As many as one-third of patients without rupture will develop pericardial effusions after MI,[468] and so the positive predictive value of pericardial effusion alone is relatively low (27.5 percent).[439] However, the absence of pericardial effusion virtually excludes VFWR as a possibility (Fig. 31-22A).[439] The presence of intrapericardial echoes consistent with blod clots increases the sensitivity and specificity for VFWR, but the positive predictive value is still only 70 percent, as those findings also may occur after infarction fibrinous endocarditis.[439,469] Echocardiography is also useful in ruling out other mechanical causes of acute hemodynamic collapse after MI, including PM or VSR.

The addition of Doppler measurements and contrast agents has increased opportunities to identify the site of ventricular wall rupture (Fig. 31-22B). Doppler may demonstrate flow from the ventricle into the pericardial sac (although as tamponade progresses, this becomes less evident). Contrast agents (such as air bubbles) may be seen in the pericardial space.[470]

### ANGIOGRAPHY

In the case of subacute rupture, few data support the use of preoperative angiography. Few long-term survivors undergo concomitant coronary procedures,[471,472] and many angiograms demonstrate normal coronaries other than the

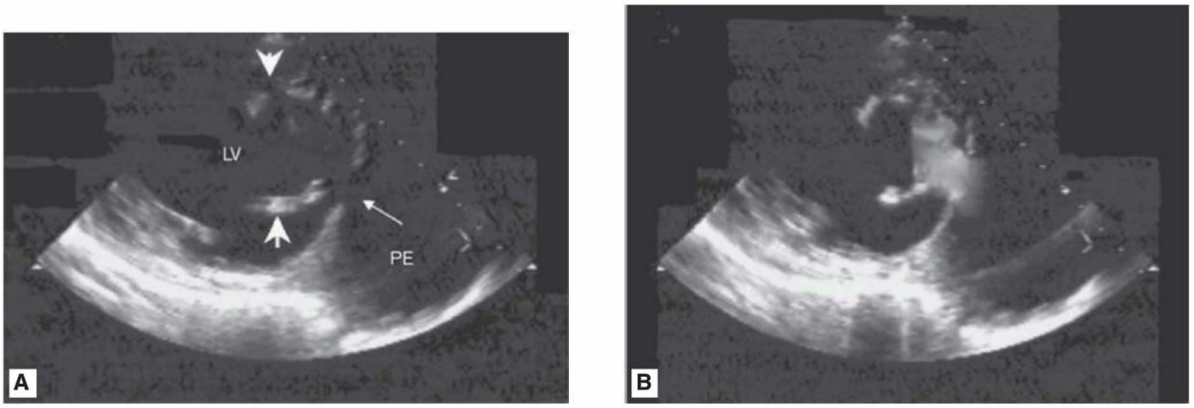

**FIGURE 31-22** Transesophageal two-dimensional (**A**) and Doppler (**B**) echocardiography illustrating ventricular free wall rupture (*white arrow*) into the pericardium from the left ventricle. White arrowheads mark the papillary muscles. Doppler imaging shows flow into the pericardium. PE, pericardial effusion; LV, left ventricle. (From Birnbaum Y, et al. Ventricular free wall rupture following acute myocardial infarction. *Coron Artery Dis* 2003;14(6):463–470.)

infarct-related artery.[473] Transfer to the operating room should not be delayed by cardiac catheterization, as outcomes depend on operative repair of the rupture rather than on concomitant coronary procedures.

### MAGNETIC RESONANCE IMAGING

Currently, magnetic resonance imaging (MRI) has little use in the setting of acute MI or subacute rupture because it is time-consuming and patients become relatively inaccessible inside the scanner. However, MRI is used with increasing frequency in the evaluation of pseudoaneurysms (Fig. 31-21). Its advantages include high resolution and image quality as well as excellent anatomic definition made possible by 3-D reconstruction techniques.[474–477]

## Medical Therapy

### ACUTE OR SUBACUTE RUPTURE

Once the diagnosis of VFWR has been made, medical management is directed toward hemodynamic stabilization. Initial therapies include aggressive IV fluid resuscitation and blood products as needed.[478] After initial stabilization, bed rest and β-blockade with maintenance of SBP between 100 and 120 may be helpful.[478] There are reports of long-term survivors without surgical repair, but those reports are rare.[478–480]

***Percutaneous Treatment.*** Pericardiocentesis is both diagnostic and therapeutic. It usually is performed with echocardiographic guidance. When pericardiocentesis demonstrates a serous pericardial effusion, rupture is excluded.[439] Therapeutically, pericardiocentesis decompresses the pericardium and decreases the threat of tamponade.[478] Despite this benefit, tamponade often recurs and proper drainage may be prevented by blood clots in the drainage catheter.[443,478] IABP placement may stabilize patients through improvements in both systemic and myocardial perfusion.[481] Murata and associates[482] described a novel technique for nonoperative management of VFWR. In two cases, injection of fibrin-glue into the pericardial space successfully stabilized patients, with resolution of pericardial effusion. Long-term follow-up of one patient treated with this technique revealed no restriction of LV motion.[483] Further experience with glue-based techniques will define the appropriate indications for such interventions, but it may be particularly applicable in patients with acute rupture, who previously would not have survived operative repair.[484]

### CHRONIC RUPTURE WITH PSEUDOANEURYSM

Traditionally, the risk of rupture led most patients with pseudoaneurysm to the operating room soon after diagnosis. However, increasing numbers of reports have described conservative management of some patients.[424,452,453] Unfortunately, no specific medical therapy has been recommended for those patients, although in light of a high incidence of stroke in the reported cases, some authors have recommended anticoagulation.[485]

## Surgical Therapy

### ACUTE OR SUBACUTE RUPTURE

In patients with acute or subacute rupture, immediate operative repair is indicated. Anesthetic induction in patients with cardiac tamponade may lead to sudden cardiovascular collapse as a result of peripheral vasodilatation. The patient should be prepared and draped before anesthetic induction. When necessary, mechanical cardiopulmonary support may be initiated via femoral cannulation before induction.[486,487] After induction, the chest and pericardium are opened rapidly, relieving the tamponade. The site of rupture is identified

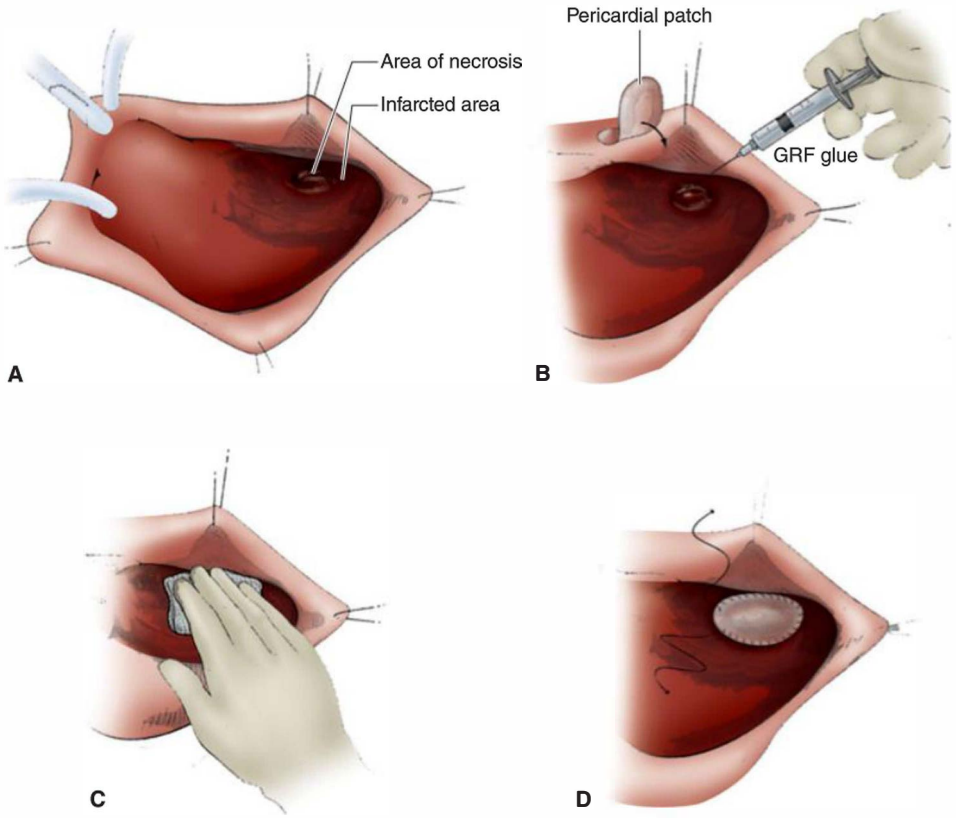

**FIGURE 31-23** Operative technique for onlay patch repair of ventricular free wall rupture. (Adapted from Figs. 21.1–21.4 in Buxton BF, Frazier OH, Westaby S (eds). *Ischemic Heart Disease Surgical Management*. Philadelphia: Mosby, 1999.)

rapidly, although in most cases the tear is sealed with clot and active bleeding will not be seen.

Several surgical approaches to the repair of left ventricular free wall rupture (LVFWR) have been advocated, including infarctectomy and patch closure, simple mattress suturing backed with felt, and an overlay patch sutured or glued into place with or without primary closure of the defect. Although many case reports describe acceptable outcomes with simple closure with pledgeted sutures,[446,488–490] in this repair the sutures are placed into necrotic myocardium; postoperative rupture would be a significant concern. Infarctectomy and patch closure do not have this shortcoming because the friable, infarcted myocardium is resected and sutures are placed into healthy tissue.[491–493] Early reports included simple closure of the defect after infarctectomy[414,473,481,494]; however, this may lead to a significant reduction in LV size and changes in LV geometry, in which case closure with a prosthetic patch is preferred. The disadvantages of this technique include the need for CPB and, at least theoretically, changes in LV geometry that may have negative long-term consequences in ventricular function, as has been seen in repair of VSR with infarctectomy.[372]

Nunez and associates were able to avoid the infarctectomy through primary closure of the defect with pledgeted sutures followed by placement of an onlay patch sutured to healthy myocardium (Fig. 31-23).[495] This technique provided good control of ventricular hemorrhage, and those authors reported survival out to 10 months.[495] Others have used similar onlay patches but have chosen not to close the myocardial tear; the patch can be secured with biological glue or sutures.[370,439,472,493,496–503]

With the advent of biological glue, many surgeons have begun to avoid the use of CPB in these patients. In posterior ruptures, CPB often is required, but with anterior ruptures, adequate closure can be obtained on the beating heart by using onlay patches secured with glue.[500] This technique appears to be safest when used in patients without a macroscopic defect in the myocardium.[504] In contrast, CPB is required when concomitant cardiac procedures are planned. Opinions about the need to perform CABG during repair of VFWR vary. Because 80 percent of ruptures occur in patients with multivessel coronary disease,[419] some authors advocate initiation of CPB and bypass of all major vessels before repair of the rupture.[488] However, as was noted above, preoperative angiography is not likely to be possible, and most reported long-term survivors have not undergone concomitant bypass procedures.[471–473] The experience with this disease is too limited to make definitive recommendations, and surgeons will

have to be guided by the clinical condition of the patient; some authors recommend a "middle ground" of bypassing palpable or clinically evident disease.[463]

### CHRONIC RUPTURE WITH PSEUDOANEURYSM

As was noted above, the natural history and risk of rupture with pseudoaneurysm are not clearly defined, and the timing of surgery depends on the perceived risk of rupture. In particular, chronic smaller pseudoaneurysms that are stable in terms of size may have a lower propensity for rupture, and patients may do well with conservative management.[424] However, surgical therapy remains the treatment of choice in patients likely to tolerate the operation. Since many patients with chronic pseudoaneurysms will be identified during a workup for coronary artery or MV disease, the decision to operate may be based on the coexistent disease.

Pseudoaneurysms may be repaired with either primary closure of the (usually thin) neck[475,505] or endocardial patch repair[475,506–508] similar to that used in a true LV aneurysm (see below). In the acute setting, the neck may not have sufficient fibrosis to provide an anchor for sutures, and so patch repair is probably a better option. When the myocardial defect is large, patch repair is preferred to minimize changes in LV geometry and relieve tension on the repair.

## Outcomes

### ACUTE AND SUBACUTE RUPTURE

The short- and middle-term results of onlay patch operations appear to be excellent. Lopez-Sendon and associates reported the results of 33 operations for ventricular rupture repaired with an onlay patch secured with either glue or sutures; 76 percent of the patients survived the operation, and long-term survival (mean follow-up 30 months) was 48.5 percent.[439] Canovas and associates recently reported middle-term outcomes for 17 patients with glued onlay patches: operative (30-day) mortality was 23.5 percent (4 of 17 patients), with one death resulting from patch failure.[500] Middle-term follow-up revealed only two additional deaths, and echocardiography revealed good ventricular function in the survivors.[500] Others have reported operative survival as high as 100 percent, although patient selection probably played a large role.[472]

### CHRONIC RUPTURE WITH PSEUDOANEURYSM

Because of its rarity, outcomes after surgical repair of ventricular pseudoaneurysm have been variable. The largest series, examining the 266 cases reported in the literature, found operative mortality of 23 percent; however, medical therapy had a 48 percent mortality rate.[485] Unfortunately, since this was a review of all *reported* cases, publication bias makes these numbers difficult to interpret. Outcomes from ventricular aneurysms may have to be relied on in estimating operative risk in this population.

## Summary

Ventricular free wall rupture is a devastating complication of MI; although it occurs uncommonly, it is the second leading cause of in-hospital death after MI. Clinical prediction of patients likely to have rupture is poor; echocardiograms should be obtained when there is any degree of suspicion. When rupture does occur, pericardiocentesis may be both diagnostic and therapeutic and may allow time for operative repair. Survival without operative repair in the setting of acute rupture is uncommon. Operative techniques include closure of the defect with or without an onlay patch. Many authors advocate sutureless repair with biological glue to adhere the patch to the epicardium. The results of onlay patch operations are excellent, with operative mortality of approximately 25 percent and little longer term mortality. Rarely, patients also may present with chronic rupture and pseudoaneurysm formation. The natural history of this entity is poorly defined, but most authors recommend repair. Techniques include primary closure of the ventricular defect and extensive repairs, as advocated for true ventricular aneurysm (see below).

# LEFT VENTRICULAR ANEURYSM

## Introduction

Although earlier reports had described enlargements of other cardiac chambers, the earliest reports of ventricular aneurysms found during autopsy were made by Galeati[509] and Hunter[510] in 1757.[511] Theories about their etiology abounded, but it was not until 1880 to 1900 that many authors independently recognized the correct relationship between coronary thrombosis, MI, ventricular scarring, and aneurysm formation.[511] The surgical correction of postinfarction ventricular aneurysm began with the use of a fascia lata graft by Beck in 1942.[512] Likoff and Bailey[513] reported the first successful aneurysm excision using a Satinsky clamp on a beating heart in 1955; that was followed by the work of Cooley and associates, who in 1958 performed the first modern aneurysm excision using CPB.[514] Since that time, repairs have been improved by a series of surgeons who have recognized the importance of normal ventricular geometry to ventricular function.[357,515–519]

Traditionally, LV aneurysm was defined as a region of myocardium exhibiting an abnormal diastolic contour with systolic dyskinesia and paradoxic bulging. However, growing experience with ventricular aneurysm as well as ischemic cardiomyopathy has led to the recognition that even large regions of akinesis without the traditional paradoxic systolic bulging can have deleterious effects on ventricular function (so-called functional aneurysm).[520] Several authors have proposed that any region of myocardial asynergy (akinesia or dyskinesia) large enough to reduce LV function be treated as an LV aneurysm.[521–523]

## Pathophysiology

The formation of LV aneuryms (whether traditional or functional) results from the remodeling process that occurs after transmural MI. This process has been divided arbitrarily into an early phase and a late phase. The early phase (less than 72 h after an infarct) is characterized by infarct expansion that may result in ventricular rupture or ventricular aneurysm.[524] The late phase (more than 72 h) involves global ventricular responses to changes in wall stress and strength, including chamber dilatation, mural hypertrophy, and changes in LV geometry that lead to poor contractile function.[525]

### EARLY REMODELING

Early remodeling results primarily from the effects of migration of inflammatory cells into the infarct zone. Necrotic myocytes initiate complement activation and free radical generation, which leads to a cytokine cascade and the migration of neutrophils into the infarct zone.[526] Neutrophil-mediated proteolysis leads to degradation of the intermyocyte collagen struts, resulting in infarct expansion within hours of infarction.[425,527]

The wall thinning and dilatation of infarct expansion lead to elevations in both diastolic and systolic wall stress (LaPlace effect). This causes a further increase in muscle fiber tension. Combined with the greater tendency for infarcted and ischemic myocytes to stretch under a constant load, progressive dilatation results until fibrosis and scarring supervene.[528] Deformation of the border zone and noninfarcted remote myocardium lead to alterations in Starling forces with adaptive changes in ventricular function, including augmented systolic shortening, activation of the sympathetic adrenergic system, and stimulation of natriuretic peptides.[525] When the region of viable myocardium is large enough, these mechanisms result in maintenance of cardiac output and systemic perfusion. However, in the longer term these mechanisms also result in the development of ventricular hypertrophy and higher myocardial oxygen demand in the remainder of the ventricle.

Infarct expansion occurs rapidly after MI. In more than 55 percent of cases, aneurysms are evident within 48 h; the remainder develop within the first 2 weeks.[520] This period forms the vulnerable period in which defects resulting from ventricular wall weakness (including rupture and aneurysm) are most likely to occur because the necrotic myocytes have not been replaced with scar. In cases in which viable, hibernating myocardium is present in the infarct zone, aneurysms seen on initial angiography may resolve over the course of several weeks.[529] Furthermore, reperfusion of the infarct zone may halt the remodeling process and prevent aneurysm formation, as reperfusion has been associated with a lower incidence of ventricular aneurysm.[529,530]

### LATE REMODELING

The late phase of remodeling in the setting of ventricular aneurysm is dominated by the response of the functioning myocardium to the presence of the aneurysm. During that time, the aneurysm becomes composed primarily of scar tissue. This leads to both systolic and diastolic dysfunction. During systole, the aneurysm fails to contract, leading to a reduced ejection fraction and cardiac output. In diastole, the aneurysm wall does not undergo normal distention, resulting in elevated LV diastolic pressure.

The normal myocardium attempts to compensate for these changes primarily with two mechanisms: myocyte hypertrophy and changes in ventricular geometry that attempt to redistribute the wall stress more evenly across the ventricle.[525] Reduction of ventricular wall stress with nitrates between 2 and 8 weeks after an infarct reduces hypertrophy,[531,532] and similar effects as well as decreased ventricular dilatation can be seen with ACE inhibitors.[533–535] Because these compensatory mechanisms may maintain cardiac output and coronary perfusion, ventricular aneurysms may remain asymptomatic for long periods. However, unless the aneurysm is small, progressive dilatation and hypertrophy ultimately result in increasing myocardial oxygen demand with progressive heart failure. The development of heart failure may occur (as it does in aortic regurgitation) with a sudden and profound presentation as the ventricle finally decompensates.[536,537]

## Clinical Features

The incidence of LV aneurysm depends on the definition and diagnostic techniques used, but approximately 10 to 35 percent of patients develop a region of systolic akinesia or dyskinesia after transmural MI.[511,520,538] Ninety percent of aneurysms occur on the anterior portion of the LV, approximately 25 percent of which occur near the apex.[539–541] Patients with ventricular aneurysm are more likely to have had a previous MI, to have a decreased ejection fraction (less than 50 percent), and to have increased LV end-diastolic pressure (LVEDP) (>21 mm Hg) compared with post-MI controls.[538]

Patients with ventricular aneurysm commonly present with CHF. Angina is also a common symptom, occurring in 44 to 98 percent of patients, usually related to obstruction of non-infarct-related arteries as oxygen demand in the dilated LV exceeds oxygen supply.[536,542,543] Other presenting symptoms include dyspnea and other symptoms of CHF as the LV decompensates and can no longer maintain the additional workload required to compensate for the aneurysm. Arrhythmias may occur in the scar tissue, leading to symptoms such as syncope, palpitations, and aggravation of angina or dypnea. Significant ventricular arrhythmias occur in 20 percent of large aneurysms but only 3 percent of smaller ones.[544] Finally, mural thrombus is found in 50 percent of patients undergoing surgery and is especially common in larger aneurysms.[511,536,545] Although this is rare, patients may present with symptoms of embolic disease, including stroke and peripheral arterial occlusion.

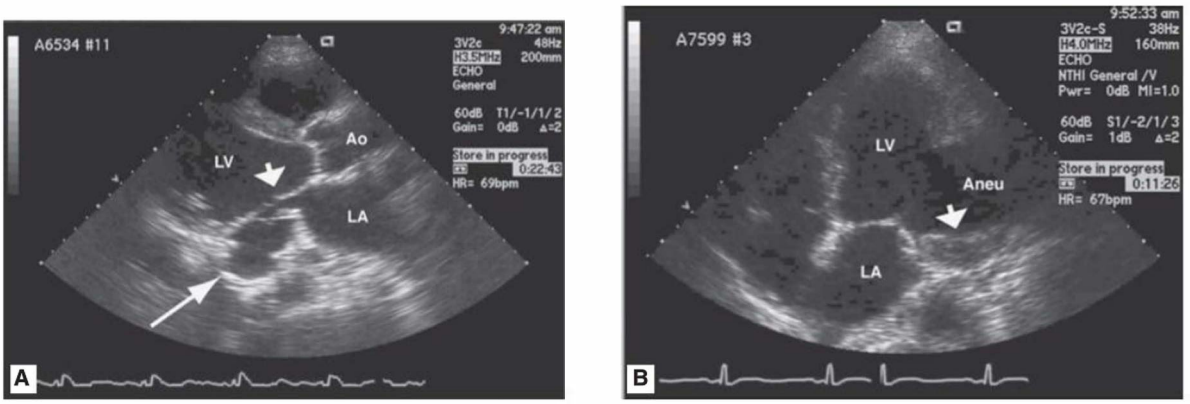

**FIGURE 31-24** Two-dimensional echocardiograms. **A.** Left ventricular pseudoaneurysm (*white arrow*) just inferior to the mitral valve annulus. The ventricular wall continues across the mouth of the pseudoaneurysm (*large white arrowheads*). Small white arrowhead indicates the mitral valve leaflets. **B.** In contrast, in a true left ventricular aneurysm, the ventricular wall forms the lateral margin of the aneurysm. Mural thrombus (*white arrowhead*) is visible along the aneurysm wall. Ao, aorta; MV, mitral valve; LV, left ventricle; LA, left atrium; PsA, pseudoaneurysm; Aneu, aneurysm.

## Diagnostic Modalities

Historically, electrocardiographic changes (Q waves and persistent ST changes in the anterior leads) and chest roentgenogram findings (LV enlargement and cardiomegaly) have been described in LV aneurysm, as have a variety of physical signs. However, these findings are not specific and play little role in the modern diagnosis of this disease.[511]

### ECHOCARDIOGRAPHY

Echocardiography is useful as a noninvasive test for mechanical complications in patients with coronary symptomatology and coronary artery disease. It can identify valvular disease, including MR, that may mimic the vague symptoms of ventricular aneurysm. In addition, it can differentiate true aneurysms from false aneurysms and evaluate for mural thrombus (Fig. 31-24).

### ANGIOGRAPHY AND VENTRICULOGRAPHY

Although echocardiography has advantages as a test that is noninvasive and easy to perform, ventriculography remains the gold standard for the diagnosis and preoperative evaluation of ventricular aneurysms (Fig. 31-25). In addition to defining cardiac function, it permits determination of coronary anatomy, allowing for optimal operative planning. Di Donato and associates[522] described a method for estimating LV aneurysm size accurately by using the centerline method. Previously, estimates of LV function and aneurysm size were made qualitatively by the cineangiographer. In their study, the extent of asynergy (A percent) was calculated as the percent length of the LV perimeter showing fractional shortening less than two standard deviations from the normal mean value. Surgical outcome correlated with A percent rather than with the presence or absence of dyskinetic motion.

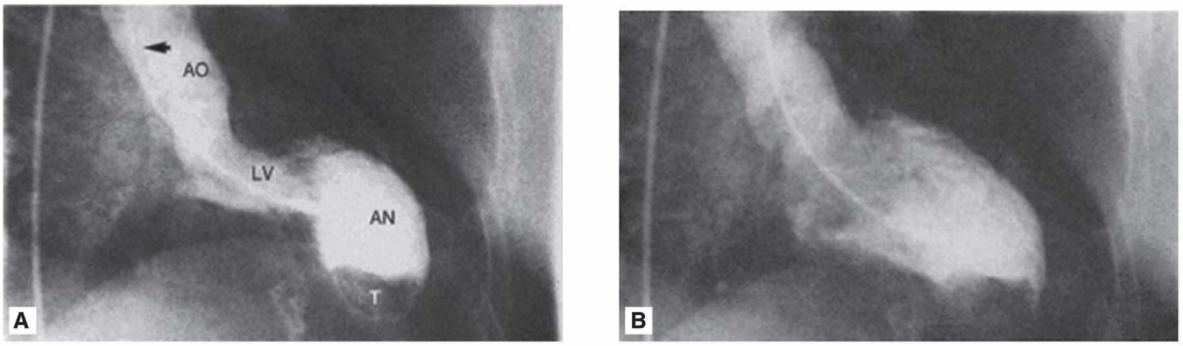

**FIGURE 31-25** Angiography of left ventricular aneurysm. The systolic image (**A**) clearly shows the large region of apical dyskinesia with mural thrombus, whereas the diastolic image (**B**) appears relatively normal. AN, aneurysm; LV, left ventricle; AO, aorta. (From Patel R, Shenoy MM. Images in clinical medicine: Left ventricular aneurysm. *N Engl J Med* 1993;329(4):246.)

### OTHER MODALITIES

Cardiacgated MRI provides highly accurate delineation of LV geometry and size and can identify mural thrombi. However, it cannot assess coronary anatomy or cardiac function adequately and therefore is not likely to supplant angiography in the near future.

## Medical Therapy

Medical therapy for LV aneurysm consists predominantly of agents directed at minimizing the deleterious aspects of LV remodeling. Nitrates have been shown to reduce myocyte hypertrophy but have not been shown to have a beneficial effect on mortality in clinical trials.[51,546] ACE inhibitors also may inhibit infarct expansion and reduce the incidence of aneurysm. Multiple studies have shown survival benefits in all patients with MI and in those with LV dysfunction.[51,546–548] Although studies have not addressed medical therapy for ventricular aneurysms specifically, standard treatments for LV dysfunction, including β-blockade and ACE inhibitors, should be used as indicated.

## Surgical Therapy

### INDICATIONS FOR OPERATIVE REPAIR

Many asymptomatic patients can be managed medically with excellent results. In 18 patients with asymptomatic ventricular aneurysms, Grodin and coworkers noted 90 percent survival at 10 years with a stable clinical course over that time; this contrasts with the 22 symptomatic patients who had 10-year survival below 50 percent.[549] However, the presence of an aneurysm involving more than 25 percent of the LV surface puts a significant strain on the remaining healthy myocardium.[536] In these circumstances it is likely that as with aortic regurgitation, a stable clinical course may be followed by abrupt decompensation with an abrupt increase in operative risk; these patients should receive operative therapy before decompensation.[536,550] However, small asymptomatic aneurysms in patients without elevated LVEDP and without the need for coronary revascularization may be managed medically. Frequent follow-up is important, as any deterioration in LV function or increase in aneurysm size should lead to surgical repair.[551] In addition, asymptomatic patients with comorbid conditions, including operative coronary artery disease and MV dysfunction, should be considered for concomitant aneurysm repair.[551]

Symptomatic patients should be evaluated for operative repair of a ventricular aneurysm; whether the aneurysm is primarily akinetic or dyskinetic, outcomes are similar.[522] Few aneurysms are too large for surgical repair. In the absence of involvement of the PMs, there is almost invariably enough ventricular muscle to sustain cardiac output.[536] Even when the contractile ejection fraction is between 0.25 and 0.30, aneurysms may be treated successfully with surgery provided that the mean pulmonary artery pressure is less than 40 mm Hg and the cardiac index is greater than 2.1 L/min; if these conditions are not met, the patient should be considered for transplantation, especially when RV dysfunction, permanent MR, and poor targets for coronary revascularization coexist.[536,544,550] Before surgery these patients should undergo right and left heart catheterization with delineation of the coronary anatomy. MR should be evaluated, and appropriate treatment planned.

### OPERATIVE TECHNIQUE

A median sternotomy is performed, saphenous vein or arterial conduits are harvested as needed, and the heart is cannulated for coronary bypass. Except in cases in which the right ventricle must be entered, a single two-stage right atrial cannula is usually sufficient. If indicated, epicardial mapping should be performed. To produce asystole and myocardial relaxation, most authors recommend cold anterograde cardioplegia with a solution containing potassium chloride.[551] A linear left ventriculotomy is then made approximately 3 to 4 cm lateral to the LAD. Mural thrombus then is removed, and blood is aspirated from the ventricle to identify positively the transition zone between viable myocardium and fibrotic scar. A variety of techniques have been described for repair of the LV after aneurysm excision.

***Plication.*** Plication consists of direct closure of the defect without aneurysm excision. Buttressed two-layer monofilament is used to plicate the scar and should be oriented to maintain normal LV geometry. It should be reserved for very small aneurysms without mural thrombus in cases in which LVEDP and LV function are largely preserved.[536]

***Linear Repair.*** In 1958, Cooley described the first successful aneurysmectomy using a linear repair with CPB. It remains a popular repair, although surgeons[551] increasingly are turning to a geometric repair (see below). A linear repair consists of excision of the aneurysm, leaving a 3-cm rim of scar tissue for fixation of the suture line. The defect then is closed with buttressed mattress sutures placed through the fibrous base. Although it is simple in concept and technique, this procedure leads to alterations in LV geometry that may have a significant impact on long-term function. In particular, the suture line approximates the lateral wall and medial (septal) wall of the LV at a point where they usually would be separated by at least a few centimeters, decreasing LV size and distorting LV geometry. Furthermore, there is no exclusion of septal paradox when the septum is involved in the scarred region.[536]

***Geometric Reconstructions.*** A number of surgeons noted high mortality after the linear repair and were troubled by the deformity in the ventricular cavity that resulted. Hutchins and Brawley[552] first brought significant attention to the problem of LV geometry after linear repair and recommended a repair described by Stoney and associates[515] in which the lateral myocardial wall was advanced down the septum to

create greater curvature and volume in the LV. Early attempts to ameliorate the problem of LV geometry after aneurysm resection included those of Daggett and associates,[357] who performed an external patch technique, and those of Komeda and associates,[553] who used an inverted T closure of the ventriculotomy to preserve the normal conical shape of the LV.

***Circular Patch Technique.*** The circular patch technique is most suitable for aneurysms of the posterior portion of the heart.[554] After debridement of the ventriculotomy rim and removal of thrombus, a Dacron patch is cut to a size 2 cm larger in diameter than the defect. Pledgeted 0 horizontal mattress sutures then are used to secure the patch, with the pledgets remaining outside the ventricular cavity. Hemostasis is obtained with a second layer of sutures as required.

***Endoventricular Patch Technique.*** Subsequently, Jatene,[555] Dor and colleagues,[523,556,557] and Cooley and coworkers[519] described techniques for ventricular reconstruction, all of which involve placement of an endocardial patch in an attempt to maintain normal LV and septal geometry. The technique advocated by Jatene involves the placement of a pursestring suture around the orifice of the aneurysm on a beating heart. Those sutures are used to bring the orifice down to a size estimated to be close to that of the original infarcted area.[536] If the aneurysm is small, it is possible simply to close the defect at this point (although this differs from a linear repair in that the pursestring brings the ventricular wall together with minimal alteration in geometry). More commonly, the aneurysm is resected and a patch is secured to the endoventricular side of the orifice. Although operating on a beating heart makes appropriate placement of the sutures easier, the large amount of prosthetic material left in contact with the pericardium increases the risk of postoperative infection and makes reoperation more difficult secondary to adhesions.[536]

Dor's technique involves slight modifications, including the invariable use of a patch for closure and extension of the patch to exclude scarred septum rather than septal plication as described by Jatene.[558] Finally, in the technique advocated by Cooley and coworkers, the sac is not excised but instead is sutured closed over the patch to augment hemostasis (Fig. 31-26).[519] The advantages of these techniques include applicability to early aneurysms when infarct tissue is friable, preservation of the LAD, and separation of prosthetic material from the sternum when the aneurysmal sac is closed over the defect. In addition, these techniques facilitate patching of infarcted interventricular septum. Recently, Alonni and associates published excellent results with endoaneurysm repair via port access surgery in seven patients.[559]

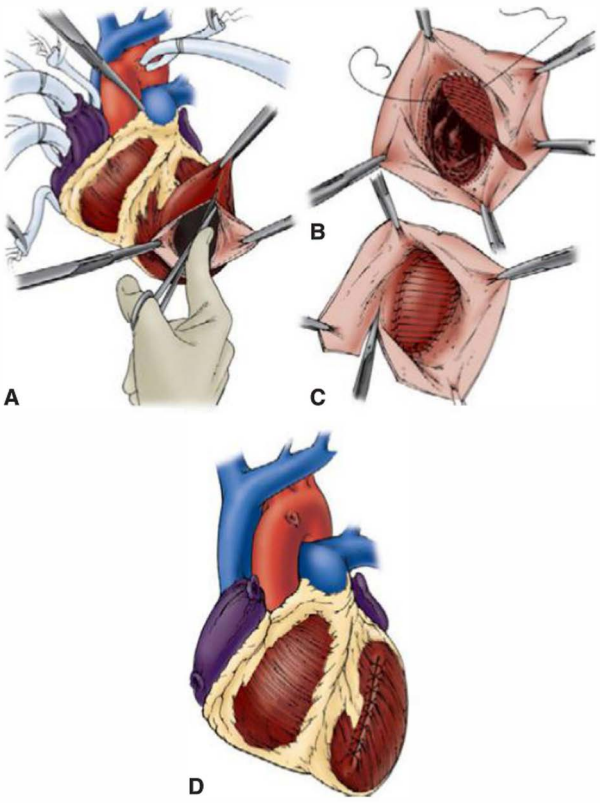

**FIGURE 31-26** Endoaneurysmorrhaphy as advocated by Cooley and associates. (Adapted from Cooley DA, Frazier OH, Duncan JM, et al. Intracavitary repair of ventricular aneurysm and regional dyskinesia. *Ann Surg* 1992;215(5):417–423.)

## CONCOMITANT PROCEDURES

Valve surgery should be performed in patients with MV disease. Repair or replacement can be performed via the ventriculotomy or by using a standard left atriotomy. Preoperative catheterization should identify patients who require concomitant CABG. Complete myocardial revascularization should be performed if possible. In patients undergoing linear repairs, the distal LAD generally is occluded by the repair. If patients have adequate distal targets, bypass may be performed, although most of these patients have significant distal disease, making bypass impossible.

## OTHER TECHNIQUES

The injection of a variety of stem cells (including fetal smooth muscle cells and bone marrow cells), as well as autotransplantation of healthy cardiomyocytes, has been reported to improve cardiac function and prevent LV dilatation in animal models.[560–563] This work has been extended to the use of bioengineered vascular smooth muscle grafts during endoventricular aneurysm repair.[564] Although experimental, this work holds promise for providing short-term recovery of normal LV geometry and preventing long-term deleterious LV remodeling.

## POSTOPERATIVE CONSIDERATIONS

Postoperatively, patients frequently require inotropic support to facilitate weaning from CPB. Dopamine may be

particularly useful for its inotropic and chronotropic effects. Abnormal ventricular compliance and an increased risk for postoperative ventricular arrhythmias in this population may decrease the effectiveness and increase the risk of higher doses of inotropes. Low-level resting tachycardia (heart rate between 100 and 120) may be required to maintain the cardiac index. If pharmacologic agents are ineffective, an IABP may be required in the short term.

## Outcomes and Prognosis

### EARLY RESULTS

Operative mortality in recent series of both linear repair and ventricular reconstruction procedures are approximately 2 to 13 percent, with most series at the lower end.[536,539,553,565–568] Multiple authors have sought to compare linear repair and ventricular reconstruction techniques; although no one has used a randomized trial, most results suggest that ventricular reconstruction provides improved results.[522,566,569,570] In a recent study of 149 patients operated on for LV aneurysm, Lundblad and associates found linear repair to be an independent predictor of both early and overall mortality (odds ratio 4.4, 95 percent CI 1.0–16.0).[566]

Other risk factors for early mortality include advanced age,[553,566] three-vessel coronary disease,[566] previous coronary artery bypass,[553] emergency operation,[566] poor preoperative ejection fraction (<0.20),[522,553] preoperative severe heart failure (NYHA class IV),[522,553,566,571] nonuse of the IMA,[522,571] MR,[522] and a history of malignant ventricular arrhythmias.[566] Cardiac failure constitutes the most common cause of postoperative death,[567] but ventricular arrhythmias and multiorgan system failure are also important.[567]

### LATE RESULTS

Long-term mortality also appears to be improved with the use of ventricular reconstruction vs linear repair.[566] Five-year mortality varies from 20 to 42 percent.[539,566,572–574] Ten-year survival is only approximately 30 percent[567,572]; however, survival in medical patients is probably worse, and although medical treatment of heart failure has improved, the mechanical dysfunction at the heart of ventricular aneurysm still must be addressed.[575] Most of these patients die of progressive heart failure or recurrent MI or experience sudden death.[567] Risk factors for long-term mortality are advanced age,[566] three-vessel disease,[566] low LVEF or preoperative heart failure,[539,566,567] high PCWP,[567] use of an IABP,[567] more than one previous MI,[566] 2+ or 3+ MR,[539] and a history of malignant ventricular arrhythmia.[539,566]

### LEFT VENTRICULAR FUNCTION

Most measures of LV function are improved after linear repair or ventricular reconstruction. The large study by Di Donato and colleagues demonstrated a significant increase in LVEF after surgery (from 36 to 50 percent) with decreased pulmonary pressures and end-diastolic volume index (EDVI).[522] Even patients with large akinetic scars (who had the worst preoperative function) benefited significantly (ejection fraction increased from 25 to 41 percent).[522] Similar improvements in LVEF,[539,573,576,577] left ventricular end-diastolic volume (LVEDV),[576] myocardial oxygen consumption,[577] and exercise tolerance[519,576] have been reported by others regardless of the technique used.

There is continuing controversy about the relative advantages of linear repair and ventricular reconstruction. No randomized data exist, and the retrospective data are plagued by problems of comparisons across different time periods, surgeons, and patient populations. Several experienced groups have published large series reporting improvement in postoperative function with the switch to ventricular reconstruction techniques.[540,541,578–580] However, other groups have reported no difference, and some have reported an increase in operative mortality.[570,581,582] It appears that acceptable results can be obtained with either technique, and the most important determinant of improvement in LV function may be the appropriate size of the LV cavity rather than the specific technique used.[540,552,583] The persistence of improvements in LV function over the long term has not been studied extensively, but in humans only mild worsening of hemodynamic variables and cardiac function has been noted 7 years after surgery.[584] This suggests that although mortality remains high, it may result more from baseline coronary disease than from worsening pump function.

## Summary

Ventricular aneurysms result from regions of infarcted myocardium that are either akinetic or dyskinetic. This has profound effects on ventricular remodeling and in most patients results in progressive heart failure in the long term. Most aneurysms develop within 2 weeks of the inciting MI, and approximately 10 to 35 percent of patients develop an aneurysm after transmural MI. Most patients present with CHF, and the gold standard for evaluation remains angiography and ventriculography; this allows for evaluation of coronary disease and optimal operative planning. Patients with asymptomatic aneurysms may be managed medically, but those with symptoms or with extremely large aneurysms (more than 25 percent of LV surface) merit operative repair. Multiple techniques for repair have been described. The most commonly used in the modern era is a geometric repair with a patch closure of the site of aneurysm resection, optimizing LV geometry and minimizing long-term alterations in LV function. Operative mortality is approximately 10 percent, and 5-year mortality ranges from 20 to 42 percent. However, most patients have significant improvements in LV function and clinical status after aneurysm resection, and the high long-term mortality probably is related to the baseline medical condition rather than failure of the surgical repair.

## MECHANICAL COMPLICATIONS OF MYOCARDIAL INFARCTION BOARD REVIEW QUESTIONS (CHAPTER 31)

1. What are the current American College of Cardiology/American Heart Association Guidelines Committee recommendations for initial reperfusion therapy in patients with three-vessel coronary disease in cardiogenic shock from AMI:
   A. Placement of DES
   B. Placement of bare metal stents
   C. CABG
   D. Balloon angioplasty
   E. No intervention

2. A 45-year-old man with a history of medically managed multivessel coronary disease presents with a new ST-elevation myocardial infarction. Approximately 7 days after his myocardial infarction, he complains of severe dyspnea. His chest x-ray demonstrates severe bilateral pulmonary edema. Physical exam is significant for a mild holosystolic murmur. Which of the following complications of myocardial infarction is he most likely to have:

   A. PM rupture
   B. VSR
   C. Ventricular free wall rupture
   D. Ventricular aneurysm
   E. Ventricular dysfunction due to myocardial stunning

3. Which of the following patients would be most at risk for VSR following myocardial infarction:

   A. A 40-year-old with a history of angina with stenoses in the LAD (80 percent), RCA (95 percent), and circumflex (80 percent), 1 week following myocardial infarction
   B. An 85-year-old without past medical history with a 90 percent LAD stenosis, 24 h following myocardial infarction
   C. An 85-year-old with a history of two previous myocardial infarctions who has a 95 percent LAD stenosis, 85 percent RCA stenosis and two marginal branches with 90-and 95 percent stenoses, 72 h following myocardial infarction
   D. A 60-year-old without past medical history with a 90 percent LAD lesion, 2 weeks following myocardial infarction
   E. An 85-year-old without past medical history with a 95 percent occlusion of the RCA, 24 h after myocardial infarction

4. A patient who is 7 days out from a large anterior wall infarction develops sudden onset of chest pain and dyspnea. Chest x-ray demonstates small bilateral pleural effusions. Echocardiography reveals a large pericardial effusion with evidence of intrapericardial blood clots. There is no evidence of MR or left-to-right shunting across the ventricular septum. At this point the patient has a heart rate of 120, blood pressure is 75/60, respiratory rate of 12. The next most appropriate intervention is:

   A. Percutaneous coronary intervention
   B. Transfer to the operating room
   C. Pericardiocentesis
   D. Placement of a tube thoracostomy
   E. Placement of an IABP

5. In patients with ventricular aneurysms, all of the following are indications for repair, EXCEPT:

   A. Symptoms of CHF
   B. Decreased LVEF <40 percent
   C. Embolic stroke in the setting of a left ventriular thrombus
   D. Increase in aneurysm size
   E. Aneurysm exceeding 15 percent of the LV surface

## ANSWERS

1. **Answer: C.** Coronary artery bypass grafting is the recommended treatment for three-vessel coronary disease and cardiogenic shock in the setting of acute myocardial infarction.
2. **Answer: A.** A patient with new-onset pulmonary edema following myocardial infarction is most likely suffering from acute MR. The murmur of MR may be subtle on physical exam. Seven days after infarction, acute onset of MR is most likely due to PM rupture, as ventricular dysfunction due to myocardial stunning should be improving rather than becoming acutely worse.
3. **Answer: B.** Risk factors for VSR include older age and a lack of previous history of angina or MI. In addition, single-vessel coronary disease is more common among patients with VSR. VSR most commonly occurs in the early post-MI period within 24 to 48 h.
4. **Answer: C.** This patient is at high risk for having a ventricular free wall rupture. While immediate operative repair of free wall rupture is indicated, only appoximately 70 percent of patients with these echocardiography findings will have a free-wall rupture. More importantly, the patient is decompensating from cardiac tamponade and needs immediate therapy to relieve the pericardial effusion. Pericardiocentesis will both treat the tamponade and enable diagnosis of the source of the effusion to direct further therapy.
5. **Answer: E.** Asymptomatic patients with small aneurysms may be managed medically with good long-term results. However, the development of symptoms (whether due directly to ventricular dysfunction or secondary processes such as embolic disease) merits operative evaluation. Also, increasing aneurysm size or decreasing ventricular function should prompt operative repair.

# 32 Aortic Valve Replacement

*William M. Yarbrough*
*John S. Ikonomidis*

## KEY CONCEPTS

- Epidemiology
  - Approximately 100,000 aortic valve replacement procedures have been performed in the United States in the last 10 years. Most patients present with aortic valve pathology that requires replacement between ages 60 and 80. Replacement for aortic stenosis is performed much more commonly (85 percent) than is replacement for aortic insufficiency.
- Pathophysiology
  - With aortic stenosis, there is a decrease in the effective valve orifice area, resulting in progressive obstruction of the left ventricle. The ventricle adapts through concentric hypertrophy, which increases diastolic stiffness and impairs the efficacy of diastolic coronary blood flow. Diastolic dysfunction precedes systolic dysfunction. With aortic insufficiency, gradual ventricular dilatation occurs, causing an increase in wall stress. This, in conjunction with the decrease in diastolic pressure, reduces diastolic coronary blood flow. With continued dilatation, fibrosis occurs, increasing ventricular stiffness and impairing diastolic relaxation. Eventually, the preload reserve of the ventricle is reached and further dilatation and fibrosis result in a decline in systolic function that may not be recoverable after aortic valve replacement.
- Clinical features
  - Aortic stenosis patients complain of combinations of symptoms of chest pain, syncope, and congestive heart failure. The life expectancy of patients with untreated aortic stenosis who present with angina is 50 percent at 5 years, 50 percent at 3 years with syncope, and 50 percent at 2 years with congestive heart failure symptoms. A small proportion of patients with aortic stenosis present with sudden death. Aortic insufficiency has a more insidious onset and usually is characterized by the development of slow congestive heart failure and fatigue symptoms. Angina pectoris and syncope are rare in these patients. These patients may be managed on medical therapy for protracted periods with an acceptable quality of life.
- Diagnostics
  - The work-up for candidates for aortic valve replacement includes echocardiography to estimate ventricular function and the degree of stenosis or insufficiency and cardiac catheterization to measure cardiac output, calculate aortic valve area, and image the coronary arteries for significant lesions. A careful oral examination or dental consultation is very important to prevent postoperative prosthetic valve infection.
- Treatment
  - Aortic valve replacement options include homograft, stented and stentless xenograft tissue, and mechanical valves. The decision to use each of these is dependent on patient age and valve preference, comorbid conditions, and contraindications to the use of anticoagulants. A variety of options are available to manage potential patient–prosthesis mismatch at the time of surgery.
- Outcomes
  - The outcomes of tissue valve replacement show 80 to 93 percent freedom from structural valve failure at 10 to 14 years. Bleeding and thromboembolic events complicate mechanical valve replacement at a rate of approximately 4 percent per patient-year. Homograft valve replacements have the highest freedom from structural valve deterioration, with rates of 81 to 93 percent at 15 years. Survival after aortic valve replacement is dependent more on patient comorbidities than on the requirement for valve replacement. Postoperative complications specific for aortic valve replacement include complete heart block (1 percent) and perivalvular leaks (1–2 percent).

## HISTORICAL BACKGROUND

### Aortic Valvotomy

The first attempt to open a stenotic aortic valve in a patient was performed by Theodore Tuffier on July 13, 1912.[1] This effort was accomplished by invaginating the ascending aortic wall with a finger and pushing the aorta through the valve. The 26-year-old male patient recovered and returned to his home in Belgium. Russell Brock dilated calcified aortic valves in humans in the late 1940s with instruments passed from the innominate artery or other arterial sources.[2] His results were initially poor, and he[3] as well as Bailey et al.[4] later used different dilators in various approaches with somewhat better results. However, the mortality for these patients remained high. Horace Smithy, a South Carolina surgeon, suffered from severe rheumatic aortic stenosis (AS). Having achieved national acclaim for the development and successful use of a valvulotome for closed commissurotomy in patients with rheumatic mitral disease, he developed an aortic valvulotome[5] and enlisted Dr. Alfred Blalock to perform the operation on him. Dr. Blalock agreed provided that he and Dr. Smithy perform the procedure together on another patient first. A patient was scheduled but unfortunately that patient died of ventricular fibrillation during induction of anesthesia. Shortly thereafter, Dr. Smithy died of complications related to his own severely stenotic aortic valve before the operation could be carried out.

### Mechanical Prostheses

In the early 1950s, Hufnagel[6] and Campbell[7] independently developed and implanted artificial valves in the descending thoracic aorta of dogs. In his paper published in 1954, Hufnagel reported a series of 23 patients starting in September of 1952 who had this operation for aortic insufficiency (AI).[8] These efforts preceded the evolution of the most successful of the caged ball valves, the Starr–Edwards prosthesis. This valve, created by M. Lowell Edwards, a retired engineer, and Albert Starr, a cardiac surgeon in Portland, OR, was originally implanted in the mitral position in August of 1960. The first clinical Starr–Edwards aortic valve implantation was performed in September of 1961.[9] Shortly after the introduction of the cage ball concept, a number of similar designs appeared in clinical use, which are beyond the scope of this chapter. However, excellent reviews are available.[9,10]

The concept of the tilting disc valve arose out of the concerns that cage ball valves were bulky and that the hemodynamics achieved were less than ideal. In an attempt to reduce the profile of these valves, a flat disc instead of a ball was used as an occluder. The earliest examples of the tilting disc concept were flat valves. These had a ring with a straight segment on which a disc was hinged much like the lid of a toilet seat. Other modifications included free-floating, polypropylene discs such as that introduced by Melrose and colleagues,[11] and other interesting designs such as those produced by Water and McLeod in Edinburgh.[12] In 1969, Bjork and Shiley produced a valve in which a free-floating disc was restrained by two low-profile M-shaped struts.[13,14] The first implantation of the Bjork–Shiley prosthesis was in 1975. In 1978, the disc profile was changed from plano-convex to convexo-concave (C-C model) and struts were modified such that the disc moved 2.5 mm downstream as it tilted.[14] In 1981, the valve ring was altered and a single heavier hook replaced the outlet strut, all of which was machined from one piece of metal with no welds (the monostrut valve).[15] Other examples of tilting discs valves included the Lillehei–Caster, Omniscience, and Omni Carbon valves. Some were removed from use because of the high incidence of thrombotic obstruction,[16] and others such as the Medtronic-Hall D16 Valve and the Bjork–Shiley C-C valves because of an unacceptable incidence of strut fractures.[17]

The earliest bileaflet mechanical valve designs were introduced by Gott and Daggett,[18] Kalke and Lillehei,[19] and Wada[20] in the early- to mid-1960s. These prostheses failed due to mechanical malfunctions and high thrombogenicity. However, from these failures arose the realization that bileaflet prostheses had hemodynamic characteristics superior to that of all of the prostheses available at the time. In 1976, the bileaflet design was modified and manufactured entirely from pyrolytic carbon.[21] Subsequent studies showed that the bileaflet design was very durable and that in addition, pyrolytic carbon was quite biocompatible and thromboresistant. The prototype pyrolytic carbon bileaflet valve, the St. Jude Medical Prosthesis, was first implanted clinically in 1977.[22] This valve has undergone a number of modifications since the original standard St. Jude valve was introduced including the lower profile Hemodynamic Plus (HP) Valve,[22] the Masters Valve (which allows internal rotation of the leaflets to get a better seating once the valve is implanted),[23] and the Regent Valve (with a modified external profile to create an even larger internal orifice area per valve size).[24] Other bileaflet valves are currently in use, such as the Carbomedics[25] (released for clinical use in December, 1986) and Sorin Bicarbon (released in 1990) models.[26]

### Bioprostheses

With the introduction of glutaraldehyde for the fixation of biological tissue by Carpentier and colleagues in 1969,[27] the use of bioprosthetic material, both porcine valves and bovine pericardium, became feasible alternatives to mechanical designs for valve replacement. The University of Padua has the most extensive experience with the Hancock standard porcine bioprosthesis, which was first clinically implanted in the aortic position in March of 1970.[28] The Hancock modified orifice (MO) valve was introduced in the wake of concerns about high postimplantation gradients with small valve sizes in the aortic position. This problem, due to the bulky muscle bar under the right coronary cusp of the valve, was reconciled with the MO design, a composite

valve that replaces the right coronary cusp with a cusp from another valve that does not contain the muscle bar. The Carpentier–Edwards standard porcine bioprosthesis was introduced in 1975.[29] Second-generation bioprostheses include the Carpentier–Edwards supra annular (SAV) porcine bioprosthesis, available since 1981,[30] the Hancock II porcine bioprosthesis, which was introduced in 1982,[31] and the Medtronic intact porcine bioprosthesis available since 1985.[32] In general, these valves offer improved zero-pressure fixation that preserves subtle but important histological features of the valve leaflets, and antimineralization treatments to reduce calcific degeneration of the valve tissue. In addition, more flexible, lower profile stent materials and reduced sewing rings are employed to create a larger effective orifice area (EOA). Numerous other porcine bioprosthesis are under evaluation.

The first bovine pericardial bioprosthesis was the Ionescu–Shiley valve developed by Marian I. Ionescu and G. Wooler in 1971.[33] In 1981, a low-profile model was released, but had a much higher rate of failure than the standard Ionescu valve. A final model III was implanted and used clinically before Shiley decided to cease the production of pericardial valves in October of 1977.[34] The Mitroflow pericardial valve was designed by Siegel and Totten and first clinically implanted in 1982.[35] The most common currently used pericardial valve, the Carpentier–Edwards pericardial valve, was first clinically implanted in Paris, France, in July 1980.[36] This valve has undergone a number of modifications, including the Perimount RSR[37] and Magna series.

The first clinically applicable bioprosthetic stentless aortic valve was the Toronto stentless porcine valve (SPV) as introduced by Dr. Tirone David at the University of Toronto in 1991.[38] This valve offered an increased EOA of the valve by minimizing sewing ring and eliminating the supporting struts. The stentless valve design consisted of a native porcine valve reinforced by a small amount of fabric sewn to the patient's annulus in a planar fashion followed by implantation of a small amount of porcine aorta around the valve commissures directly to the patient's own native aorta. Other stentless valves currently in use include the Medtronic free-style porcine prosthesis[39] and the Edwards Prima Plus porcine prosthesis.[40] Other stentless valves, such as the ATS-3F Therapeutics stentless equine bioprosthesis,[41] have been evaluated in clinical trials and are available for clinical use.

The first experimental animal studies involving homograft aortic tissue were performed by Lamb et al. in 1952, who implanted an allograft aortic valve into the descending aorta of the dog.[42] This was followed within 3 years of the clinical reimplantation of the allograft aortic valve into the human descending aorta by Murray[43] and subsequently by Heimbecker and associates in Toronto.[44] The technique for subcoronary implantation of allograft tissue using the single suture method was reported by Duran and Gunning in 1962[45] and implemented the same year by Donald Ross[46] in patients with a freeze-dried aortic valve, a feat performed shortly thereafter by Barrett–Boyes.[47] Sterilization of homograft valves has undergone a number of changes from formaldehyde, chlorhexidine, propiolactone, methylene oxide, gamma radiation, and storage using a carbon dioxide freezer at –70°C. Currently, most homograft valves are cryopreserved with low-dose antibiotics.

## EMBRYOLOGY AND ANATOMY

The aortic valve develops from three swellings or ridges of endomyocardial tissue at the proximal orifice of the septating truncus arteriosus. These ridges become hollowed out and reshaped to form three thin-walled cusps or pockets at approximately the sixth to seventh week of development.[48] The three aortic valve cusps are semilunar in shape and are named depending on whether or not the sinuses they subtend give rise to coronary artery ostia. Therefore, a right and a left coronary aortic cusp and one noncoronary cusp exist. The base (semilunar point of attachment to the aorta) of the leaflet is approximately one and a half times as long as its free margin. Portions of the noncoronary and a portion of the left coronary cusps are in continuity with the anterior leaflet of the mitral valve (the aorto-mitral continuity), which is an anatomical consideration that can become very important in the case of valve replacement for endocarditis. The aortic valve annulus is variable in its definition but is toughest in approximately the noncoronary section, constituting tissue between the left and right fibrous trigones of the heart. The ascent of the aortic attachment of the noncoronary cusp toward the right coronary/noncoronary commissure lies directly over the atrioventricular conduction system, which sits in the right fibrous trigone or central fibrous body of the heart. Sutures placed too deeply in this area during valve replacement will result in atrioventricular conduction block. It is important to understand that the aortic valve leaflets are attached to the aortic root in a scalloped fashion. Most techniques of valve replacement involve conversion of this scalloped aortic annulus to a relatively planar orientation, which can have important anatomic considerations. Certain stented bioprostheses are designed to maintain some of the scalloped architecture when implanted. Each aortic valve leaflet has a small nodular excrescence at its midportion called the node of Arantius or the nodulus Arantii.[49]

An aortic valve leaflet has three layers: the fibrosa or arteriosa (arterial side), the spongiosa (middle), and the ventricularis (ventricular side). These layers are composed of varying proportions of elastin, collagen and glycosaminoglycans. The outer layers of the valve cusps are covered in endothelial cells oriented perpendicular to the direction of blood flow.[50]

## ETIOLOGY AND PATHOPHYSIOLOGY

Aortic valve replacement (AVR) is performed in patients in whom there is an underlying morphologic or anatomic abnormality of the aortic valve independent of its

supporting structures, which causes it to become stenotic or regurgitant.

## Aortic Stenosis

AS typically arises as a result of degenerative calcification in the elderly or as a result of rheumatic degeneration in those individuals that have a history of rheumatic fever. Certain congenital conditions also predispose to AS. The most common of these is congenital bicuspid aortic valves, which occur in approximately 5 percent of the population.[49] It is believed that bicuspid aortic valves create abnormally turbulent flow during systole, which in turn causes recession of the leaflet intimal lining and predisposes the valve to calcification and development of stenosis. Irrespective of the cause, failure of the aortic valve to open completely subjects the left ventricle to a persistent and abnormally high pressure load that results in the manifestation of two distinct processes.[51–53] The first process is adaptive and is characterized by left ventricular (LV) hypertrophy aimed at off-setting the inciting pressure overload while the second process is maladaptive and is associated with continued myocyte hypertrophy in combination with progressive myocardial fibrosis, a process known to reduce ventricular compliance and to contribute to impairments in diastolic filling.[52,54–59] As LV wall thickness increases, further reductions in diastolic compliance are observed, the efficacy of diastolic coronary blood flow is impaired, and coronary flow reserve is reduced in the setting of increased oxygen requirements by the larger cardiomyocyte mass. As a result of these responses, patients may actually suffer from heart failure symptoms in the absence of overt LV systolic dysfunction. Without appropriate and timely surgical intervention, chronic LV pressure overload secondary to AS, with the attendant signs and symptoms of diastolic dysfunction, can progress to frank systolic heart dysfunction, a particularly ominous condition. In addition, severe ventricular hypertrophy may create intracavitary gradients proximal to the valve, which further compound ventricular unloading and that may not be correctable with AVR.

The effects of aortic valve stenosis on myocardial structure and function, prior to, and following AVR, have been extensively chronicled.[55–57] Krayenbeuhl and colleagues examined patients with AS prior to AVR and established that patients with AS exhibited significant increases in myocyte diameter and interstitial fibrosis compared to control patients while Villari and associates reported that LV relaxation was significantly prolonged prior to surgical correction.[56,57] These investigations linked changes within the cellular and extracellular compartments with the clinical syndrome of pressure overload induced diastolic dysfunction. Moreover, they also demonstrated that corrective surgery abolished many of these preoperative characteristics though to different degrees and over variable time courses.[55] Importantly, these investigations demonstrated that pressure overload induced abnormalities within the myocardium persist years beyond surgical correction.

## Aortic Insufficiency

Isolated AI usually resolves as a consequence of structural abnormalities of the aortic valve, causing leaflet elongation and prolapse as seen with myxomatous degeneration or in various connective tissue disorders such as Marfan syndrome. Other causes include infective endocarditis, traumatic disruption of a valve leaflet from severe acceleration/deceleration injuries, rheumatoid arthritis, Reiter's syndrome, ankylosing spondylitis, psoriasis, and Takayatsu's disease. Patients with calcified degenerative aortic valves may undergo leaflet perforation or tearing, especially in the belly of the leaflet, which results in combined stenosis/regurgitation.

Acute severe incompetence of the aortic valve causes a large volume of diastolic flow reversal into the left ventricle. The ventricle does not have time to adapt to this sudden event and a rapid rise in diastolic pressure occurs, causing the pulse pressure to decrease forcing early mitral valve closure to prevent back flow into the left atrium. There is a concomitant increase in heart rate and a decrease in cardiac output. The result is a rapid onset of congestive heart failure.

Chronic, progressive valve incompetence allows time for the accommodation of a smaller gradation in flow reversal. Thus, gradual ventricular dilatation occurs, with preservation of diastolic compliance such that end-diastolic pressure is not elevated in well-compensated AI. The enlarging ventricular chamber causes an increase in wall stress (as an extension of Laplace law), which will result in some ventricular hypertrophy, but overall the chamber diameter to wall thickness ratio continues to increase. The preceding events, in conjunction with the decrease in diastolic pressure, will reduce diastolic coronary blood flow. With continued dilatation, fibrosis occurs, which increases ventricular stiffness further and impairs diastolic relaxation. Eventually, the preload reserve of the ventricle is reached and further dilatation and fibrosis result in a decline in systolic function, which may not be recoverable with AVR.

# CLINICAL FEATURES

## Aortic Stenosis

Patients with AS typically present to physicians in their 60s and 70s. Patients complain of combinations of symptoms composing the classic triad of chest pain, syncope, and congestive heart failure. Chest pains in the form of classic angina pectoris are the initial symptom in 50 to 70 percent of patients. Syncope is the presenting symptom in 15 to 30 percent of patients. The life expectancy of untreated AS in patients presenting with angina is 50 percent at 5 years, 50 percent at 3 years with syncope, and 50 percent at 2 years with congestive failure symptoms such as exertional dyspnea, peripheral edema, orthopnea, and paroxysmal nocturnal dyspnea.[60] A small proportion of patients with AS present with sudden death, most likely due to life-threatening arrhythmias

resulting from severe LV hypertrophy. However, this seldom occurs in patients who have not had antecedent symptoms. In patients who have congenital conditions predisposing to AS, such as congenital bicuspid aortic valves, presentation may occur 10 to 15 years earlier.

## Aortic Insufficiency

AI has a more insidious onset and is usually characterized by the development of slow congestive heart failure and fatigue symptoms.[61] Angina pectoris and syncope is rare. The patients may be managed on medical therapy for protracted periods of time with an acceptable quality of life. It is possible (but becoming less common) for patients with AI to be managed nonoperatively to the point where the myocardium is so decompensated that surgical treatment becomes untenable.

# DIAGNOSTIC MODALITIES

## Physical Examination

### AORTIC STENOSIS

Patients with AS present with a typical murmur, which consists of a blowing crescendo–decrescendo type pattern best heard in the left sternal border with radiation to both carotid arteries. The heart is hypertrophied but not enlarged, so typically patients do not have palpable enlarged hearts with this condition. Palpation of the pulse reveals low volume and a delayed upstroke (*pulsus parvus et tardus*), owing to the gradual severity of the stenosis.

### AORTIC INSUFFICIENCY

With AI, gradual LV dilatation is observed. On cardiac auscultation, an early diastolic murmur radiates to the point of maximal intensity (apex), and may be associated with a mid-diastolic murmur caused by fluttering of the anterior mitral valve leaflet (Austin–Flint murmur). In addition, a number of interesting physical exam signs have been noted in these patients, including "water-hammer" (Corrigan) pulses with wide pulse pressures and low diastolic pressure, DeMusset's sign (bobbing of the head), Muller's sign (wobbling of the uvula), pistol shots, Durozier's sign (murmur heard over the femoral arteries), and Quinke's sign (cyclical blanching of the nail beds).

An extremely important aspect of the physical examination in patients being considered for aortic valve surgery is the examination of the mouth and teeth. Dental disease is a major cause of prosthetic valve endocarditis (PVE) and no AVR, unless under extremely urgent circumstances, should be performed without having appropriate dental clearance when deemed necessary.

AS and AI are not associated with any specific serum laboratory abnormalities.

## Diagnostic Studies

### AORTIC STENOSIS

The chest radiograph shows calcification of the aortic valve, and a subtle convexity of the LV silhouette due to LV hypertrophy. The electrocardiogram shows LV hypertrophy, and left or right bundle branch block if the calcific process causing stenosis involves the conduction system significantly. Transthoracic echocardiography shows the calcified valve with poorly mobile leaflets in the parasternal long-axis view. A short-axis view of the valve may show whether the valve is bi- or tricuspid. Continuous-wave Doppler is used to calculate valve gradients and valve area. The peak valve gradient is calculated as a function of the highest measured flow velocity (defined as peak gradient = $4V^2$, where $V$ = velocity), which is often demonstrated in the four-chamber view. The mean gradient is calculated as a function of the area of the continuous wave flow velocity curve. Valve area is calculated by the continuity equation and utilizes both continuous wave- and pulse wave Doppler. The calculation entails multiplying the LV outflow tract (LVOT) area by the LVOT flow velocity as measured by pulse-wave Doppler and then dividing the derived value by the continuous wave velocity. The accuracy of echocardiographic measurements is confounded by the presence of extensive calcification, basal septal hypertrophy, and probe orientation. In addition to the above, severe LV hypertrophy may manifest with subvalvular, intracavitary gradients. If present, this may present a significant challenge to the surgeon at operation.

At catheterization, aortic valve area is estimated at cardiac catheterization using the Gorlin formula, which, in the simplified version, is defined as valve area = cardiac output/gradient$^{-2}$.[62,63] A caveat to the Gorlin equation is that it is very sensitive to flow. Therefore, patients who have reduced ejection fraction may have a falsely reduced valve area, as calculated by the Gorlin equation. In these cases, correlation to the echocardiographic calculation is helpful.

### AORTIC INSUFFICIENCY

The degree of AI can be estimated by echocardiography, where the rapidity of equilibration of aortic and LV diastolic pressure determines the degree of insufficiency. Accordingly, a diastolic pressure half-time of <300 ms, a short mitral deceleration time (<150 ms), and premature closure of the mitral valve all indicate severe AI. LV cavity dilatation is also assessed.

At catheterization, the degree of AI can be estimated by the degree of leakage of contrast into the left ventricle during diastole. However, this estimation is relied upon less frequently in lieu of the echocardiographic methods described above.

Patients with AS and AI should be initially evaluated with a transthoracic echo. If transthoracic echocardiography confirms the suspected diagnosis and the patient's symptoms warrant operation, it is logical to proceed with coronary catheterization to exclude the presence of coronary artery

disease (CAD). In females less than 40 years of age and males less than 35 years of age with no cardiac risk factors, coronary catheterization can be omitted relatively safely.

## MEDICAL (NON SURGICAL) THERAPY

### Aortic Stenosis

There is no acceptable medical therapy for symptomatic AS. The use of antihypertensive medications and angiotensin converting enzymes inhibitors must be carried out with caution because of the risk of profound hypoperfusion. Use of beta-blockade may slow the heart rate and provide for a longer systolic interval potentially resulting in higher stroke volume in patients with stenotic valves. Digitalis glycosides may provide a mild positive inotropic effect, which may be of benefit. Percutaneous valvotomy[64] will reduce a tight stenosis to moderate stenosis with a final valve area between 0.7 and 1.1 $cm^2$, still inferior to the valve area obtained with a prosthetic valve replacement, which usually provides a valve area over 1.5 $cm^2$. The hospital mortality associated with this procedure varies from 3.5 to 13.5 percent, and within 24 h 20 to 25 percent of the patients have at least one serious complication, in particular vascular complications at the puncture site. Despite a relatively modest improvement in valve function, the quality of life benefit rarely lasts beyond a year. This technique is useful for improving the clinical status of patients with severe AS as a preamble to conventional valve replacement.[65] Without valve replacement, however, the prognosis is poor. Currently, it is generally felt that valvotomy alone does not change the natural course of the disease. The poor midterm results are mainly due to the clinical status of the patients and to the moderate and transient improvement in valve function obtained by valvotomy.[66] More recently, and as discussed below, percutaneous valve deployment has been successfully employed in patients deemed too high-risk for surgery.[67] These valves consist of pericardial valve substitutes that are mounted on expandable stents. Results of these procedures are encouraging, but significant long-term results are not available for this technology.

### Aortic Insufficiency

The therapy for aortic valve regurgitation is primarily afterload reduction with vasodilating agents to discourage regurgitation and prevent pathologic remodeling of the myocardium.[68]

## INDICATIONS FOR SURGERY

### Aortic Stenosis

All patients with severe aortic valve stenosis and symptoms should be considered for traditional valve replacement. These patients tend to have aortic valve areas of less than 1 $cm^2$ associated with a mean gradient exceeding 40 mm Hg.[68] Asymptomatic patients with AS meeting these criteria should also be considered for valve replacement secondary to the small but real incidence of sudden death associated with the natural history of this lesion. The benefits of early surgical intervention for asymptomatic patients with severe AS are clearly identifiable in a clinical study recently reported by Kang and associates.[69] These investigators identified patients with severe asymptomatic AS and compared the long-term outcomes of those treated with conventional therapy versus those treated with early elective valve replacement. Importantly, the latter group realized a significantly higher estimated actuarial 6-year cardiac mortality compared to those patients treated with conventional therapy.[69] Thus, early surgical intervention for asymptomatic patients with severe AS and relatively low operative risk may be a worthwhile treatment strategy.

### Aortic Insufficiency

Severe AI associated with gradual ventricular dilatation and at least New York Heart Association Class II symptoms of fatigue and congestive heart failure are deemed appropriate indications for surgery. In addition, symptomatic, moderate AI with mild-to-moderate (EF >25 percent) LV dysfunction should be referred for AVR. A symptomatic patients should be considered for surgery if there is LV systolic dysfunction or severe LV dilatation (end-diastolic dimension >75 mm or end-systolic dimension >55 mm).[68,70–73]

## SURGICAL THERAPY

### Positioning, Incisions and Cardiopulmonary Bypass

The patient is placed in the supine position. Monitoring lines such as a radial arterial catheter and pulmonary arterial catheter can be placed in the holding area under sedation or after the patient is brought into the operating room. Despite excellent advances in cardiothoracic anesthesia, the occasional patient with severe AS will suffer cardiac arrest during anesthetic induction. It is therefore advisable, in cases of severe AS, for the surgeon to be immediately available from the time the patient is brought into the operating room. The patient's chest, abdomen, perineum, and lower extremities are prepped and draped in sterile fashion. Median sternotomy is the classic mode of access to the heart, but minimally invasive approaches such as upper hemisternotomy[74] and right parasternotomy[75] have been described. Tacking only the right side of the incised pericardium to the retractor or skin allows the ventricular mass to rotate posteriorly and improve access to the aortic root. The patient is systemically heparinized to reach a blood activated clotting time (ACT) of 480 s. Cardiopulmonary bypass is established using dual-stage or

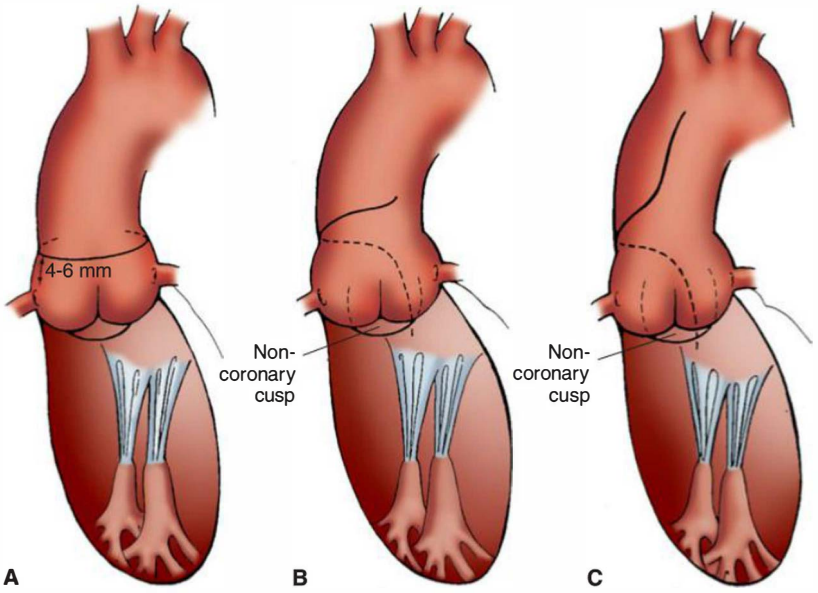

**FIGURE 32-1** Aortotomy incisions. (Reproduced with permission from David TE. Mechanical and bioprosthetic aortic valve replacement. In: Edmunds LH (ed). *Cardiac Surgery in the Adult*. New York: McGraw-Hill, 1997:859–910.)

bicaval cannulation with a LV vent placed across the mitral valve via the right superior pulmonary vein or through a stab incision in the LV apex. Mild-to-moderate systemic cooling (32°C) is used. If the valve is not regurgitant, cold blood cardioplegia should be delivered antegrade via the aortic root for more uniform myocardial distribution, then intermittently via a retrograde coronary sinus catheter for the duration of the cross-clamp period. If the retrograde catheter cannot be inserted blindly, options include bicaval cannulation and insertion of the retrograde coronary sinus catheter across the visualized coronary sinus orifice, or delivery of antegrade cardioplegia via perfusion catheters positioned or sewn into the coronary ostia. Numerous approaches to aortotomy have been described, the most common being the oblique aortotomy and near-transection aortotomy (Fig. 32-1). The oblique aortotomy begins in the anterior midline of the ascending aorta or just along the left anterior side and extends to the right and inferoposterior into the midportion of the noncoronary sinus. The near-transecting aortotomy should be made 1.0 to 1.5 cm above the origin of the right coronary artery for the best visualization. Therefore, added dissection is required on the anterior surface of the aorta to identify the right coronary artery takeoff, which can occasionally result in damage to the right coronary artery necessitating either repair or vein graft bypass of the right coronary artery. The near-transecting aortotomy is relatively easy to close but troublesome bleeding may occur posteriorly, which can be difficult to manage. In addition, if a small aortic root is encountered such that annulus enlargement is necessary, a right-angle incision must be made in the aorta and extended across the annulus, which can be very challenging to close later. Finally, since the sino-tubular junction is 10 to 15 percent smaller in diameter than the annulus, occasionally it will be very difficult to pass an appropriately sized aortic valve across the aortotomy to the annulus, especially if the aorta has lost some of its elastic properties due to calcification. The oblique aortotomy eliminates many of these concerns and is recommended by the authors. The aortic valve is inspected and the locations of the coronary ostia are identified. The valve is then carefully excised, taking care not to button-hole the aorta or damage the aorto-mitral continuity by incising too deeply. Careful debridement of all calcific matter is then undertaken where necessary followed by irrigation with cold saline to remove particulate matter (Fig. 32-2). The choice of valve and techniques of implantation are discussed below. Systemic rewarming is begun at an appropriate point in the implantation procedure so as to not impose extra time waiting for the patient to reach normothermia prior to separation from cardiopulmonary bypass. Following valve implantation, a careful inspection is performed to confirm correct seating of the valve and ensure that both coronary artery ostia are unobstructed. Also, a final check for the absence of residual particulate matter should be undertaken. The aortotomy is closed with running polypropylene suture and a de-airing vent is placed in the most anterior portion of the ascending aorta. The ventricular vent is removed. A warm cardioplegic infusion is given and the cross-clamp is removed with the patient placed in the Tendelenburg position. Ventricular and atrial pacing wires are placed and mechanical ventilation is resumed. De-airing maneuvers such as lung hyperinflation, side-to-side shaking of the chest, and manual agitation of the heart are performed with the heart partially ejecting. Transesophageal echocardiography is very helpful in assessment of de-airing, and also

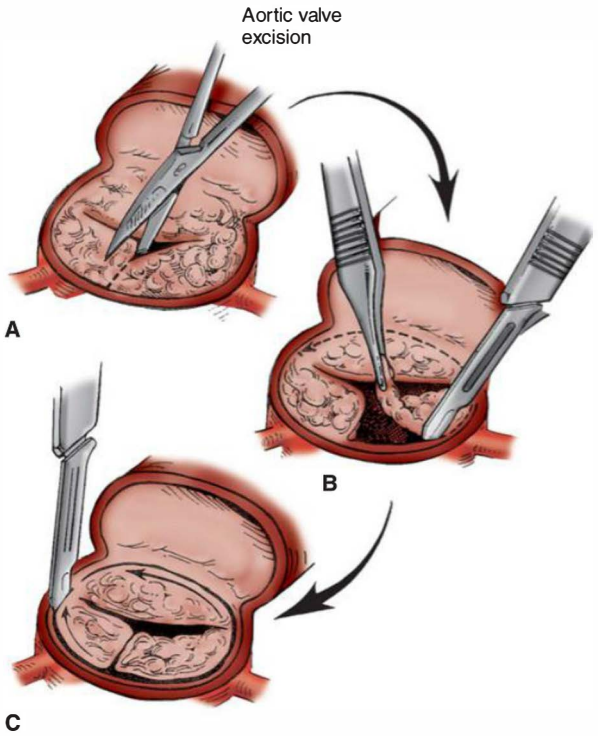

**FIGURE 32-2** Technique of excision of the aortic valve. (Reproduced with permission from David TE. Mechanical and bioprosthetic aortic valve replacement. In: Edmunds LH (ed). *Cardiac Surgery in the Adult*. New York: McGraw-Hill, 1997:859–910.)

in the interrogation of the valve for correct leaflet function and absence of perivalvular leaks. The patient is weaned from bypass at a systemic temperature of 36.5°C with good ventilation parameters. Protamine is given slowly by the surgeon directly into the ascending aorta, and the patient is decannulated. Meticulous hemostasis is obtained, a midline mediastinal drain (36F thoracostomy tube) is placed, and the patient is closed in the standard fashion.

## Which Type of Valve to Use?

Subcoronary homograft aortic valves are technically more difficult to implant than stented and stentless bioprostheses and should be considered for younger patients in centers that have extensive experience with homograft valve replacements.

Prosthetic valves have the advantage of relative ease of implantation. Bioprosthetic valves have no requirement for anticoagulation postoperatively but there are two drawbacks associated with these valves. The first is the introduction of a residual transvalvular gradient (especially with smaller valve sizes), which may impede the rapidity and extent of LV mass regression after valve replacement. The second drawback, the true "Achilles' heel" of tissue bioprostheses, is structural valve deterioration requiring reoperation for valve re-replacement. The latest-generation tissue bioprostheses such as the Carpentier–Edwards bovine pericardial[76–78] and Hancock II[31,79] porcine valves are comparable in results and have 80 to 93 percent freedom from structural valve failure at 10 to 14 years. These failure rates are accelerated in younger patients and in patients with renal failure. This type of valve is clearly most appropriate for older patients (i.e., greater than 70 years of age). However, concomitant cardiac disease (e.g., CAD) lowers the age at which one tissue valve will suffice for the patients' lifetime by 5 to 10 years.[80] Also, concomitant use of oral lipid lowering agents appear to have an important protective effect, with reduction of valve deterioration.[81,82] Having stated the above, the risk of operative mortality with isolated aortic valve reoperation is only 5 to 10 percent,[83–85] making tissue valve replacement a reasonable option even in younger patients not interested in taking oral anticoagulants and also in centers that do not perform a high volume of more complex aortic valve and root procedures.

Mechanical valves leave significant residual transvalvular gradients in smaller sizes as with stented bioprostheses, and all require oral anticoagulation. Use of oral warfarin is associated with a significant incidence of bleeding and thromboembolic complications.[86,87] A recent long-term retrospective review performed by Toole and colleagues reported that freedom from thromboembolism and bleeding at 25 years was 69 ± 5 percent and 67 ± 3 percent, respectively, in patients that underwent AVR with a St. Jude Medical mechanical prosthesis at a single-center institution.[86] Thus, a younger individual requiring AVR must make a choice between accepting the risk of an aortic valve reoperation with bioprosthetic valves versus the risk of bleeding and thromboembolic complications related to long-term oral use of warfarin.

## Valve Implantation Techniques and Results

### STENTED AORTIC VALVE REPLACEMENT

Following excision of the native aortic valve, the annulus is measured using the sizers provided by the company for the valve type selected. Valve sutures are placed in horizontal mattress fashion across the remaining aortic annulus and sequentially placed across the sewing ring of the prosthesis. The prosthetic valve is then carefully seated so as to avoid obstructing the coronary artery ostia, followed by tying and cutting of all of the sutures and closure of the aorta. Certain valves are designed to be implanted in an intraannular position (such as certain St. Jude models), necessitating placement of everting (aorta to ventricle) sutures, and others are designed for supraannular seating (such as the Carpentier–Edwards pericardial prostheses), requiring placement of noneverting (ventricle to aorta) sutures. Pledgetted or nonpledgetted sutures are used; there are no conclusive data supporting superiority of one over the other. In addition, some surgeons implant the prosthesis with a continuous running suture (Fig. 32-3). While it is intuitively obvious that

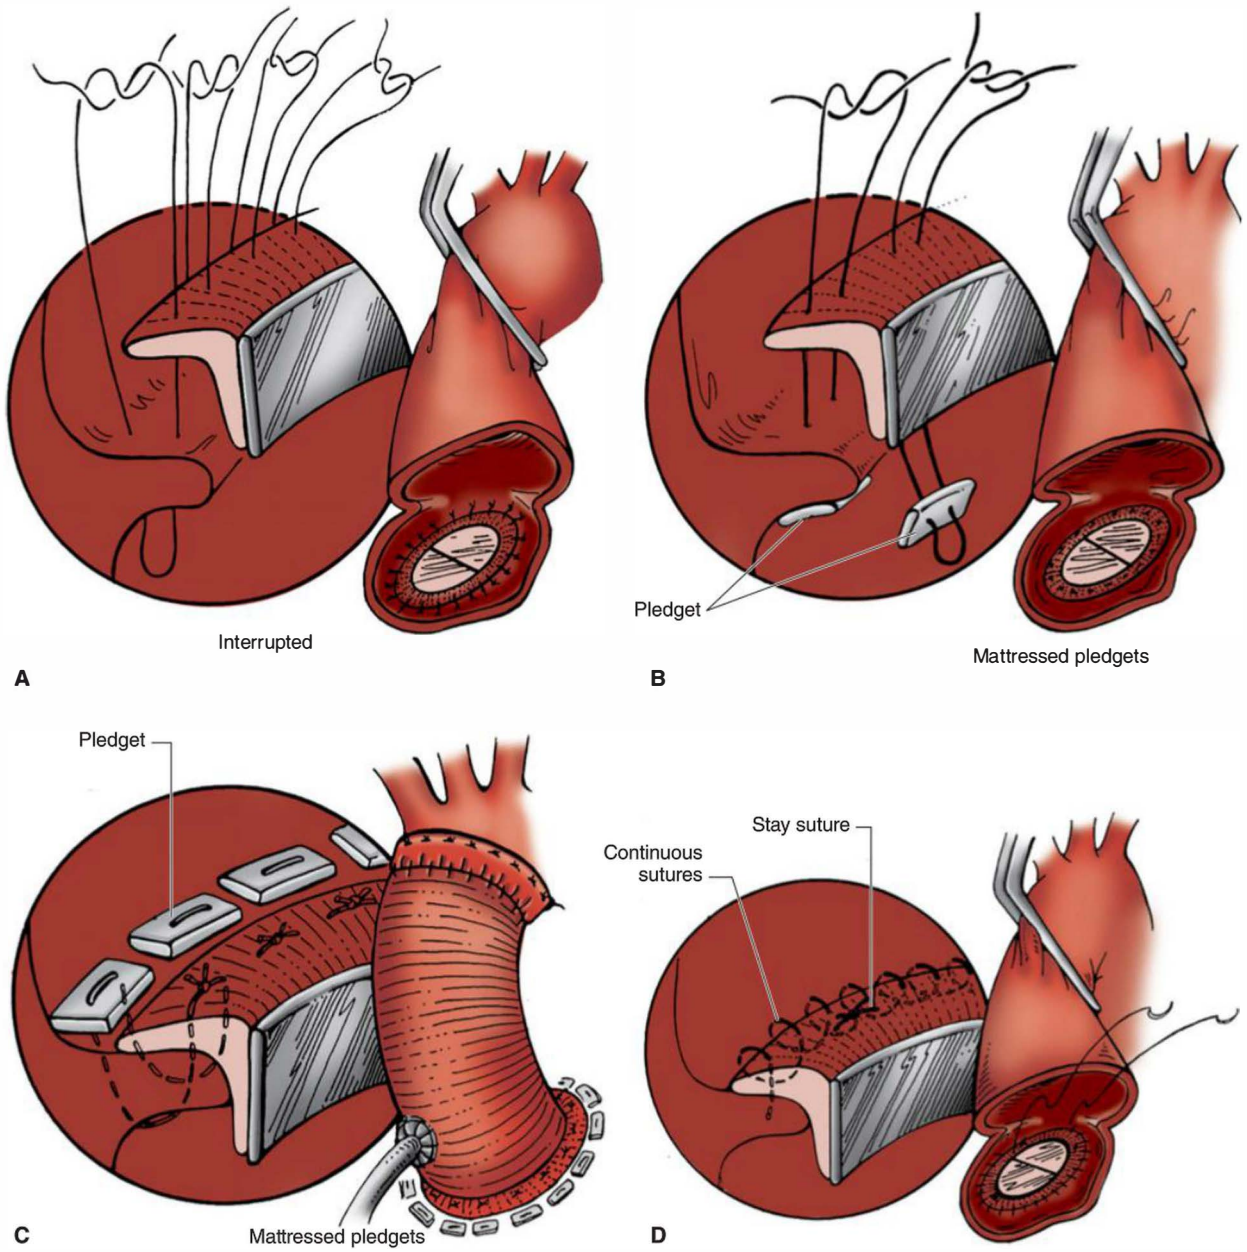

**FIGURE 32-3** Annular suturing techniques. **A.** Interrupted sutures. **B.** Noneverting mattressed pledgets. **C.** Everted mattress pledgets with replacement of ascending aorta and aortic valve. **D.** Continuous running suture. (Reproduced with permission from David TE. Mechanical and bioprosthetic aortic valve replacement. In: Edmunds LH (ed). *Cardiac Surgery in the Adult*. New York: McGraw-Hill, 1997:859–910.)

the largest valve size possible should be implanted, patients with severe LV hypertrophy resulting in intracavitary (i.e., subannular) gradients may actually be reliant on the stenotic native valve to impose sufficient afterload to prevent systolic ventricular collapse before ejection of an adequate stroke volume. In this uncommon situation, it may be appropriate to implant a *smaller* valve to impose a higher residual transvalvular gradient to encourage proper emptying of the ventricle. Alternatively, an interventricular septal myectomy/myotomy may help eliminate the intracavitary gradients in these unusual situations.[88]

The results with stented tissue prostheses continue to improve with each successive iteration. The latest-generation tissue bioprostheses such as the Carpentier–Edwards bovine

pericardial[76–78] and Hancock II[31,79] porcine valves are comparable in results and have 80 to 93 percent freedom from structural valve failure at 10 to 14 years.

Important clinical results pertaining to the use of mechanical valves in the aortic position primarily focus upon risks associated with bleeding and thromboembolic events. The longest data are available for the St. Jude mechanical prosthesis, where actuarial freedom from reoperation, thromboembolism, and bleeding following AVR at 25 years is 90 ± 2 percent, 69 ± 5 percent, and 67 ± 3 percent, respectively.[86]

### THE ST. JUDE STENTLESS VALVE

This valve is usually implanted via a transecting aortotomy approximately 1.0 to 1.5 cm distal to the origin of the right coronary ostium. After the native valve is excised, the sewing ring is attached in planar fashion at the aortic annular level with simple interrupted sutures. Following this (since this valve has no supporting stent), the valve is fixed to the patient's own aorta by sewing the rim of porcine aorta to the patient's aorta. The valve must therefore be carefully seated with the first set of interrupted sutures so that the second suture line does not obstruct the coronary ostia with proper orientation of the valve leaflets. This valve is therefore more challenging to implant than the stented prostheses, but offers the advantage of lower valve gradients, especially with smaller valve sizes.[89] The most recent data show freedom from hemodynamically significant valve insufficiency to be 82.5 percent at 9 years with 90.1 percent freedom from reoperation.[90] Anticoagulation is not required with this valve.

### MEDTRONIC FREE-STYLE PROSTHESIS

The Medtronic free-style prosthesis preserves most of the porcine aortic root and is not reinforced by stented or prosthetic fabric. The Medtronic free-style prosthesis offers the advantage of tailoring to multiple operations, including full aortic root replacement and trimming of the prosthesis for subcoronary valve replacement. The subcoronary operative technique is similar to that for the St. Jude stentless aortic valve except that the free-style aorta is scalloped to allow for both coronary ostia on the left and right sinus but typically not scalloped over the noncoronary sinus. Results of the Medtronic free-style prosthesis used as a full aortic root replacement are available to 8 years.[91] At this time, freedom from AI was 100 percent, and there were no cases of structural valve deterioration observed, with 100 percent freedom from reoperation.[91] Comparison with the St. Jude stentless valve suggests less insufficiency and lower transvalvular gradients with the free-style prosthesis.[92] Anticoagulation is not required with this valve.

### SUBCORONARY HOMOGRAFT AORTIC VALVE REPLACEMENT

For insertion of a homograft, it is generally recommended that a transecting or near-transecting aortotomy be used, though some authors have described the use of a lazy incision starting anteriorly and going to the patient's right, but ending at a level well above the expected top of the allograft commissure. By following resection of the aortic valve, the aortic annulus can be sized with a Hagar dilator or any convenient prosthetic valve sizer. To correct for the thickness of the LVOT muscle the allograft should be 2 to 3 mm smaller than the measured size of the annulus. At this point, the allograft ventricular outflow tract muscle should be trimmed to debulk it, but leave enough support for suturing and attachment of the valve cusps. Approximately 5 to 7 mm of outflow tract should be left below the valve cusps to allow adequate suturing to the annulus. In addition, if there is residual anterior leaflet of the mitral valve, this can be excised in a planar fashion. Some authors recommend that the homograft not be implanted in anatomical fashion, but rather that it be rotated 120° counterclockwise so that the outflow tract muscle does not abut onto the septum of the interventricular septum of the recipient. Following this, stay sutures are usually placed at 120° intervals in the graft corresponding to the nadirs of the commissures for orientation. Suturing of the homograft to the annulus can be performed in continuous fashion with running 4-0 polypropylene suture or interrupted fashion with running 4-0 polyester sutures placed in simple interrupted fashion. This may be facilitated by inversion of the entire homograft into the LVOT of the recipient, thus making visualization for suturing much easier. Following this, the homograft sinuses are trimmed away so as to not obstruct the left and right coronary ostia and the residual homograft aorta around the commissures is sutured to the native aortic wall with a running 4-0 polypropylene suture. The aortic wall in the area of the noncoronary sinus can be left untrimmed to facilitate implantation. Although homograft aortic valve placement can be technically challenging, results with this technique are excellent with freedom from reoperation rates in adults of 81 to 93 percent at 15 years,[93] with no anticoagulation required.

## Postoperative Care and Surgical Results

Immediate postoperative care should focus on control of hypertension (for which intravenous sodium nitroprusside or nicardipine is most commonly used) and maintenance of adequate filling pressures (central venous pressure 10–15 mm Hg, pulmonary capillary wedge pressures in the 15–18 mm Hg range). Dual-chamber pacing is required in a small proportion of patients who leave the operating room in conduction block. Often this resolves within 24 to 48 h. If conduction block persists greater than 4 to 5 days, permanent pacemaker insertion should be considered. In patients with no conduction disturbances, pacemaker wires can be removed on the third or fourth postoperative day. The patient should be placed on telemetry for the duration of the hospital stay, however. The mediastinal tube is removed for outputs less than 150 mL/24 h period.

Patients with mechanical valves are started on oral warfarin on the second postoperative day. Use of daily aspirin

coupled with a target international normalized ratio (INR) of 2.0 to 2.5 provides satisfactory anticoagulation and minimizes long-term bleeding and thrombotic events. Patients with bioprosthetic valves can be managed with aspirin alone, with no warfarin required.

The 30-day (early) mortality for AVR varies from 2 to 5 percent. This number is approximately doubled with redo operations. Preoperative variables independently predictive of early mortality include advanced age, renal insufficiency, New York Heart Association class III or IV status, poor ventricular function, concomitant CAD, and aortic cross-clamp time.

Reoperation for mediastinal hemorrhage should be required in less than 5 percent of cases. Perivalvular leaks occur in 1 to 2 percent. Complete heart block requiring pacemaker insertion occurs in about 1 percent in most series. Stroke occurs in approximately 1 to 2 percent of patients. There is no practical pharmacological strategy for the prevention of postoperative atrial fibrillation, which occurs up to one-third of the time (in patients with no previous history). Careful correction of electrolytes and chemical cardioversion with intravenous and oral amiodarone is preferred and successful 90 to 95 percent of the time. Patients should then be maintained on oral amiodarone for approximately one month by which time the threat of recurrent atrial fibrillation should be resolved. In patients requiring warfarin, use of amiodarone will make it very difficult to manage the INR, and consideration should be given to alternative antiarrhythmics such as procainamide or sotalol. Patients with persistent atrial fibrillation despite attempts at chemical and electrical cardioversion should be maintained on oral warfarin until either the arrhythmia resolves or electrical cardioversion can be performed.

## Patient–Prosthesis Mismatch

Important objectives of AVR are to minimize postoperative gradients and optimize and accelerate the normalization of LV mass regression. Occasionally, the situation arises where the implanted prosthetic valve has a gradient that is sufficiently severe so as to prevent a resolution of the physiology associated with valvular disease resulting in "patient–prosthesis mismatch." Patient–prosthesis mismatch is expressed in terms of the EOA obtained from charts published by each valve company. The EOA is standardized to body surface area (EOAI) and is suggested to be present for EOAI <0.85 to 0.90 $cm^2/m^2$.[94] A number of studies have attempted to investigate whether insertion of a small prosthesis influences short- and long-term survival. Given the fact that early and late survival after AVR is usually related more to concomitant disease processes in the valve itself, it is not surprising that many studies have not found a relationship between early and late survival in aortic valve prosthesis size. A very large study from the Cleveland Clinic by Medallion and Colleagues was unable to detect an adverse impact on survival of moderate patient–prosthesis mismatch.[95] In contrast, a study by Kratz and colleagues suggested that patients with a body surface area of greater than 1.9 $m^2$ who received the St. Jude Valve size 19 or 21 mm had a greater probability of late sudden death.[96] The study by Adams and colleagues found that insertion of a 19-mm stented bioprosthesis or mechanical valve with elderly men with AS was associated with a higher operative mortality and therefore recommended that an annulus enlarging procedure be performed in these patients.[97] However, it is important to remember that performance of an annulus enlarging procedure increases the mortality and morbidity associated with AVR and this should be kept in mind when considering this procedure. More recently, three large studies have helped to clarify the survival effect of patient–prosthesis mismatch on survival. Rao and associates[98] examined a cohort of 2981 patients undergoing AVR; they observed that smaller prosthesis–patient size was associated with greater operative mortality but did not affect overall 12-year survival. Hanayama and colleagues found, in a study of 1129 patients, that prosthesis–patient size did not influence survival, New York Heart functional class, or LV mass index.[99] Finally, Blackstone et al. examined data on 13,258 AVRs from nine data sources to address the question of prosthesis–patient size and mortality after AVR.[100] In this study, 30-day mortality increased 1 percent to 2 percent when indexed orifice area decreased to less than 1.2 $cm^2/m^2$ or standardized orifice size decreased to less than –2.5 Z. However, no expression of prosthesis–patient size was associated with reduced intermediate-term (0.5–5 years) or late-term (5–15 years) survival. In contrast, patient risk factors, such as age, had a profound effect on survival.[100]

Rather than considering the impact of valve prosthesis on survival, efficacy of regression of LV hypertrophy may be a more sensitive indicator of the adequacy of a selected prosthesis. Regression of LV mass after AVR is demonstrated within the first few weeks after surgery and extends out to about 6 months postoperatively.[101,102] The effects of prosthesis size on regression of the LV mass have proven to be somewhat controversial, as some authors have found that insertion of 19 and 21 mm stented and mechanical valves are associated with rates of regression similar to those observed with use of larger prostheses.[103,104] On the other hand, other studies have shown slower regression of LV mass.[105] What is clear is that reverse LV remodeling occurs over a variable time course after AVR for AS.[55] For example, in a seminal clinical investigation, Monrad and colleagues observed significant reductions in LV muscle mass at both intermediate (1.6 ± 0.5 years) and late (8.1 ± 2.9 years) time points as compared to values obtained in the same patients prior to valve replacement.[55] Similarities in LV muscle mass values between AS patients treated with AVR and control subjects was only observed at late time points suggesting that reverse LV remodeling occurs over a period of years. Controversies pertaining to patient–prosthesis mismatch are further confounded by the fact that the labeling of prosthetic valves and valve sizes do not bear a consistent relationship to the internal diameter of the valve orifice, which is probably the most important

hemodynamically significant dimension in terms of postoperative gradients.[106] For example, the internal diameter of a St. Jude standard mechanical valve that is labeled as 21 mm is actually 16.7 mm and the internal diameter of the MO Hancock II Porcine that is labeled as 21 mm is 18 mm. These discrepancies are particularly important in the management of a small aortic root in which insertion of an unnecessarily small prosthesis may result in very high postoperative gradients. In addition, comparison of the hemodynamic characteristics of various valve types become very difficult to judge based on these parameters.

In the light of the above, the impact of patient–prosthesis mismatch of postoperative outcomes following AVR remains somewhat controversial. EOA index may be used to identify those patients having a "small aortic root" in the operating room, hence helping the surgeon plan the appropriate valve replacement strategy. Following calculation of the patient's body surface area, excision of the diseased aortic valve and annular debridement, the aortic annulus is sized using the appropriate sizer for the valve of intended use. The EOA for this valve size is then taken from a chart published by the valve company. If the EOAI is less than 0.85 to 0.90, the aortic annulus may be considered to be small.

## Management of the Small Aortic Root

The fundamental goal of the management of a small aortic root is to avoid insertion of an unnecessarily small prosthesis. In general, the surgical options include use of a small, stented prosthesis, mechanical dilatation of the aortic root, implantation of stentless tissue valves, supraannular positioning of the valve replacement device, implementation of an annulus enlarging procedure, and in certain cases, application of the apicoaortic conduit technique. A useful rule of thumb is to remember that increasing the valve size by two increments in general results in the reduction of cardiac stroke work of approximately 40 percent, roughly equivalent to the insertion of an intraaortic balloon counter-pulsation device.

### USE OF A SMALL STENTED PROSTHESIS

Given the above discussions, it may be appropriate in certain situations to accept implantation of a small prosthesis that by calculation would result in patient–prosthesis mismatch. Examples of such situations would include elderly, inactive patients, patients with multiple other comorbidities in whom a fast, relatively simple operation is mandatory for the best outcome, or an aortic root that is so calcified that other valve replacement options may be technically impossible.

### MECHANICAL DILATATION OF THE AORTIC ROOT

Anecdotal reports have documented successful insertion of larger prosthesis after mechanical dilatation of the aortic root.[107] There are, however, very little data regarding the overall safety of this procedure and the amount of annulus enlargement achievable. Caution must be exercised when considering this option.

### IMPLANTATION OF STENTLESS TISSUE VALVES

When compared to stented bioprostheses, stentless bioprostheses in general have been confirmed to be hemodynamically superior to various valve sizes. Because of the obliteration of the thick stent with stentless tissue valves, it is often possible to implant a larger valve with a larger internal orifice area than if the stentless valve were used, thus resulting in lower postoperative gradients.[108,109] For example, in patients in which a 19-mm Carpentier–Edwards supraannular pericardial valve fits tightly into the annulus, it is usually possible to fit a 21 or 23 mm St. Jude stentless valve. Successful implantation of this valve is also dependent on the aortic root tissue being pliable and not extensively calcified such that suturing to it is possible.

### SUPRAANNULAR POSITIONING OF THE VALVE PROSTHESIS

Because the noncoronary sinus at its nadir may be lower than the nadir of the left and right aortic sinuses, the prosthesis can sometimes be implanted in the supraannular position within the noncoronary sinus.[110] The prosthesis is then sutured along the aortic annulus and the left and right coronary sinuses, but attached by pledgetted mattress sutures with the pledgets outside the aorta in the noncoronary sinus. This technique may allow implantation of a prosthesis that is one size larger than the size of the aortic annulus. Because the prosthesis crosses the aortic annulus, improper debridement of the annulus in this area may result in paravalvular leaks. A residual shelf of annular tissue will still exist under the prosthesis, which may contribute to a subvalvular gradient.

### ANNULUS ENLARGING PROCEDURE

The Nicks[111] procedure allows for implantation of a prosthesis that is approximately two sizes larger than the measured size of the aortic annulus. This involves the extension of the aortotomy into the nadir of the noncoronary sinus and into the basal third of the anterior leaflet of mitral valve. An autologous pericardial patch or Dacron patch is fashioned in tear-drop shape and the wide portion of the tear drop, up to 4 cm in transverse diameter is positioned downward into the mitral valve. Valve sutures or polypropylene sutures are then used to suture the patch along to the anterior leaflet of the mitral valve across the annulus and up the ascending aorta. Valve implantation sutures are placed across the patch itself in addition to the remainder of the annulus and the remainder of the aortotomy is closed incorporating the Dacron patch (Fig. 32-4).

A second type of annulus enlarging procedure known as the Manouguian[112] procedure involves extension of the aortotomy more posteriorly to the commissure of the non- and

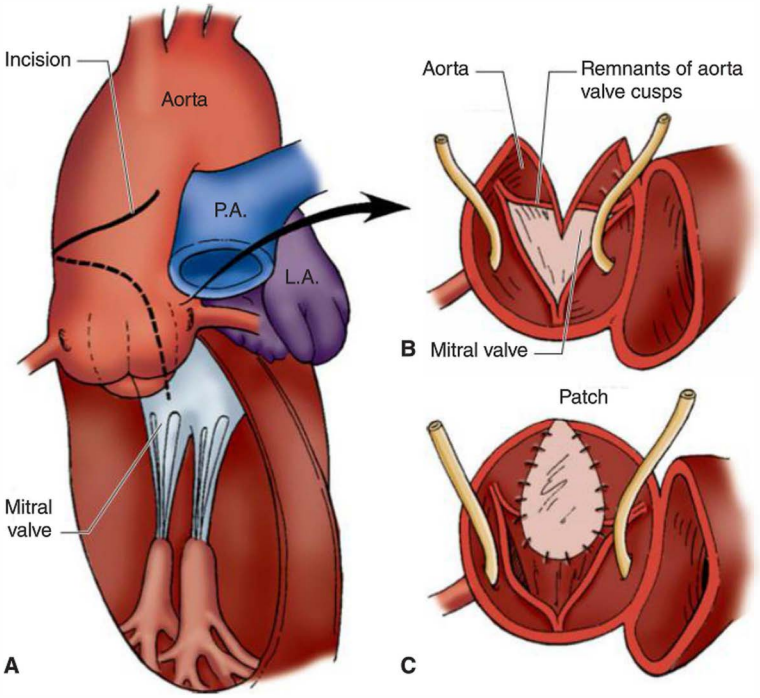

**FIGURE 32-4** Patch enlargement of the aortic annulus at the noncoronary sinus (Nicks procedure). **A.** The aortotomy incision continues downward toward the middle noncoronary sinus. **B.** The incision crosses the aortic annulus into the mid-mitral portion of the anterior mitral leaflet to the roof of the right atrium. **C.** The incision has extended into the upper third of the mitral leaflet. The width of the patch should not exceed twice the length of the incision into the anterior mitral leaflet. (Reproduced with permission from David TE. Complex operations of the aortic root. In: Edmunds LH (ed). *Cardiac Surgery in the Adult*. New York: McGraw-Hill, 1997:939–957.)

left coronary cusps. The incision is then carried through the aortic–mitral septum and onto the anterior leaflet of the mitral valve for up to 2 cm, which also opens the roof of the left atrium. A pericardial patch is then sutured along the mitral valve incision and the aortotomy as with the Nicks procedure. The prosthesis is then secured to the patch with horizontal mattress sutures that may be first placed through the opened roof of the left atrium, thus closing the atriotomy in the process. Alternatively, the atriotomy can be sutured to the patch with a second suture line. The remainder of the aortotomy may then be closed.

A third more radical approach to the small aortic root is known as the Konno–Rastan procedure or aortoventriculoplasty.[113] Its use in the small aortic root associated with aortic valve disease is becoming rare and is, in general, reserved only for enlargements in patients with congenital AS who present later in life for AVR or with other forms of complex congenital heart disease. Here the enlarging incision is made to the left side of the right coronary artery and into the ventricular septum and free wall of the right ventricle. Next, a patch is used to repair the intraventricular septum and a second patch is used to close closure of the right ventricular free wall defect as well as completing the annular enlargement.

As stated previously, it is important to remember that the operative risk with AVR may be increased with an annulus enlarging procedure, with one series quoting 3.5 percent operative risk without annulus enlargement compared to 7.1 percent with annulus enlargement.[114]

### VENTRICULAR APICOAORTIC CONDUIT

Finally, in patients in whom it is not possible to deal with an excessively small aortic root, such as with fibrous tunnel formation, tubular hypoplasia of the ascending aorta, and recurrent aortic valve stenosis unrelieved by aortic root repair or a valvotomy, ventricular apical aorta conduits have been used as a procedure of last resort.[115,116] The patient is approached by a left lateral thoracotomy based on the fifth intercostal space. A valved conduit is then sutured in end-to-side fashion to the descending thoracic aorta. Following this, cardiopulmonary bypass is established and a second graft is sutured to the apex of the left ventricle with the aid of induced fibrillation. The two conduits are then trimmed to length and sutured together, completing the operation (Fig. 32-5). The transthoracic approach gives direct access to the descending aorta and avoids a redo sternotomy. The technique, which is relatively simple to perform, does not compromise major coronary arteries, the conduction system, or other valves; and may be useful in patients who are not good candidates for other, more conventional procedures.

## Aortic Valve Replacement with Concomitant Coronary Artery Disease

Many patients with aortic valvular disease have concomitant CAD, but the data are limited regarding optimal strategies

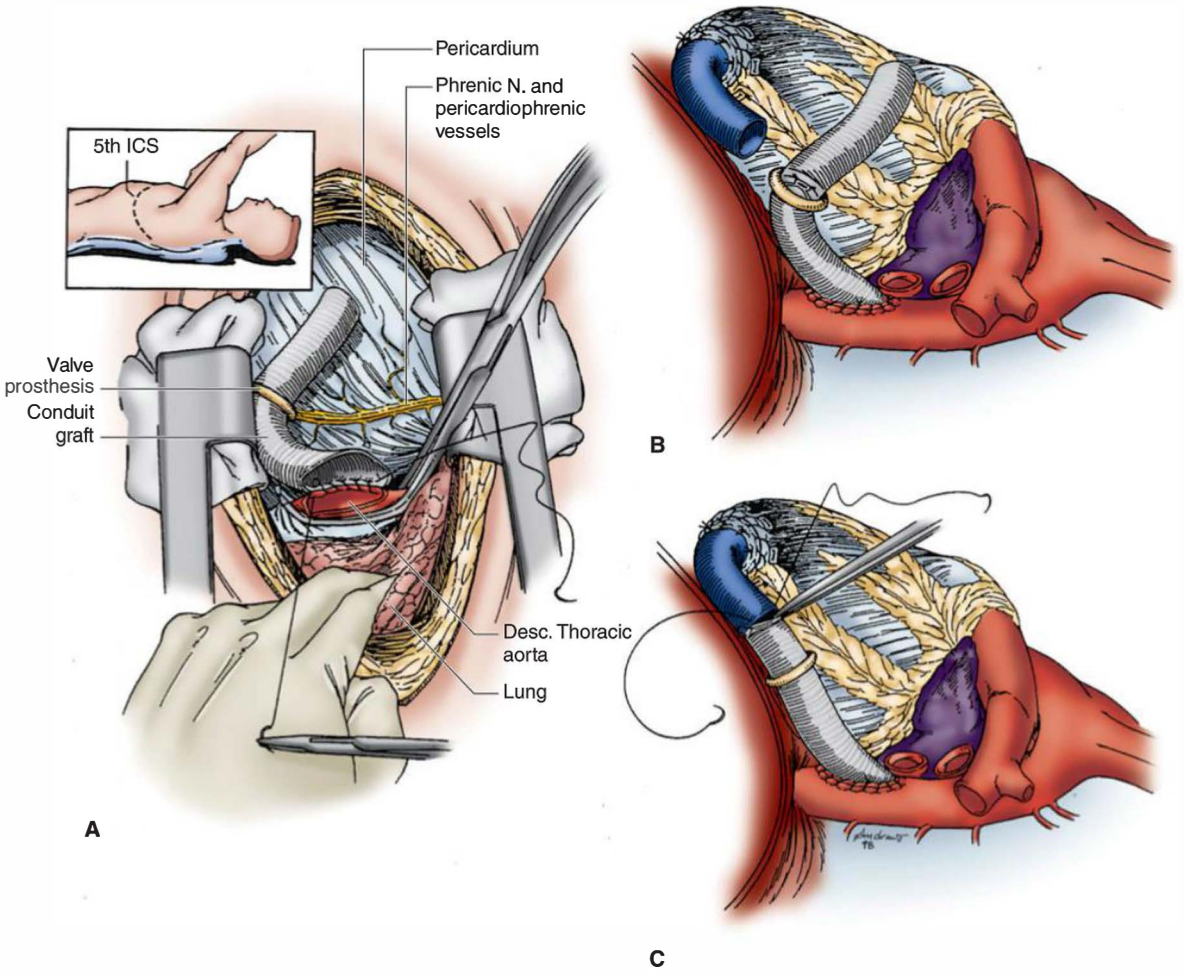

**FIGURE 32-5** Placement of apicoaortic conduit. **A.** After positioning patient in the right lateral decubitus position, the left hemithorax in entered through the fifth intercostal space. The descending thoracic aorta is partially occluded, and the valved conduit is anastomosed with a continuous 3-0 or 4-0 polypropylene suture. **B.** Under cardiopulmonary bypass, the rigid prosthesis is attached to the apex of the left ventricular via interrupted, pledgeted mattress and continuous sutures. Ventricular fibrillation is induced to facilitate the ventricular attachment. Temporary occluding clamps are used on the grafts during completion of the anastomoses. **C.** The prostheses are then connected with a continuous suture. (Reproduced with permission from Cooley DA, Lopez RM, Absi TS. Apicoaortic conduit for left ventricular outflow tract obstruction: Revisited. *Ann Thorac Surg* 2000;69:1511–1514.)

for diagnosis and treatment of CAD in such patients. Ischemic symptoms in patients with aortic valvular disease may have multiple causes, such as LV chamber enlargement, increased wall stress or wall thickening with subendocardial ischemia, and right ventricular hypertrophy. Because angina is a poor marker of CAD in these patients, coronary arteriography is recommended in symptomatic patients before AVR, especially in men older than 35 years of age, premenopausal women older than 35 years of age with coronary risk factors, and postmenopausal women.[68]

Greater than one-third of patients with AS undergoing AVR surgery have concomitant CAD. Population studies have shown that more than 50 percent of patients >70 years old have CAD. Combined coronary artery bypass surgery at the time of aortic surgery or AVR has had little or no adverse effect on operative mortality. In addition, coronary bypass grafting at the time of AVR reduces the rates of perioperative myocardial infarction, operative mortality, and late mortality and morbidity, compared with patients with significant CAD who do not undergo revascularization at the time of AVR. Incomplete revascularization is associated with greater postoperative systolic dysfunction and reduced survival rates after surgery compared with patients who receive complete revascularization.[117,118] Over the past decade, improved anesthesia and myocardial preservation techniques have been associated with reduced overall operative mortality,[119] and

it has become standard practice to surgically bypass all significant coronary artery stenoses when possible in patients undergoing aortic valve surgery.

It is well agreed upon that all patients undergoing coronary artery bypass surgery who have severe AS, symptomatic or not, should undergo AVR at the time of revascularization.[68] Decision-making is more difficult in patients with mild-to-moderate AS who have CAD requiring coronary bypass surgery. Controversy persists regarding the indications for so-called "prophylactic" valve replacements at the time of coronary bypass surgery in such patients.

It is difficult to predict whether a given patient with CAD and mild AS is likely to develop clinically significant AS after revascularization. The natural history of mild AS is variable, with some patients manifesting a rapid progression of their disease, with a decrease in valve area of up to 0.3 $cm^2$/year and an increase in pressure gradient of 15 to 19 mm Hg/year.[120] The average rate of reduction of valve area is 0.12 $cm^2$/year,[121] but the rate of change in an individual patient is difficult to foresee. Phillips et al. reviewed 100 patients who underwent AVR after previous coronary artery bypass grafting (CABG) where the mean valve gradient was <25 mm Hg at the time of initial operation. The mean time interval to reoperation was 9.0 years (range 1.4–21 years) and the overall operative mortality was 7.0 percent. The authors concluded that given the relatively long time interval between the two operations and the significant decline in reoperative mortality rate in recent years, an expectant approach to concomitant AVR–CABG is warranted.[122] Karagounis and associates reviewed 200 patients requiring CABG who all had AS with peak gradients less than or equal to 40 mm Hg. Of these, 46 underwent combined AVR–CABG at first operation. Over a median follow-up period of 4.2 years, none of the patients who had CABG only at first operation required reoperation for AVR. From these data, the authors recommended CABG only for patients with mild AS.[123] In contrast, Ahmed and colleagues followed 40 patients with mild-to-moderate AS who underwent CABG without AVR. Eleven patients (27 percent) in this study group required reoperation for AVR.[124] Similarly, Hochrein and associates noted a 24.3 percent AVR reoperation rate over a 6-year period in patients receiving CABG alone versus 3 percent in patients who underwent AVR–CABG at initial operation.[125] The results of these two studies suggest that AVR is a reasonable option at the time of initial CABG in this patient population.

Smith et al. performed a decision analysis based on the Society of Thoracic Surgeons national database and have submitted the following recommendations. For patients under 70 years old, AVR for mild AS is recommended if the peak valve gradient is 25 to 30 mm Hg. For older patients, the threshold gradient increases by 1 to 2 mm Hg/year of age. Also, CABG only is favored in patients with slow (<3 mm Hg/year) progression of AS, in contrast to those with rapid progression (>10 mm Hg/year), who should have combined AVR–CABG, with the possible exception of patients >80 years old who have valve gradients <25 mm Hg at the time of surgery.[126] The choice of prosthesis does not influence overall survival, but a bioprosthetic valve is likely more appropriate in this setting because of increased complications related to the requirement for anticoagulation with mechanical valves,[126] and because the decreased patient longevity in patients with significant CAD undergoing AVR with makes structural valve deterioration much less likely.[80]

## Aortic Valve Replacement in End-Stage Renal Disease

AS is common in patients undergoing maintenance dialysis. Abnormalities include annular and valvular thickening, and calcification of one or more of the heart valves, thereby leading to stenosis with or without concomitant regurgitation.

Many predisposing factors are associated with valvular disease in dialysis patients, the most noteworthy being secondary hyperparathyroidism.[127,128] Valvular calcification is associated with an elevated calcium–phosphorus product, hypercalcemia, vascular calcification, and elevated phosphate levels, all findings that can occur in patients with marked secondary hyperparathyroidism. Valvular calcification may also be found in the absence of secondary hyperparathyroidism, particularly among those with bone disease, older patients, and those who have undergone dialysis for a longer duration. The association with a dynamic bone disease may be related to the increasing utilization of calcium-containing phosphate binders and the subsequent development of hypercalcemia.[129] Additional factors that may enhance the development of valvular heart disease in this patient population include the presence of one or more of the following conditions: hypertension, hyperlipidemia, LV hypertrophy, hypertrophic cardiomyopathy, mitral valve prolapse, high cardiac output states, anemia, or infective endocarditis.

The use of bioprosthetic valves in hemodialysis patients was classified as a class III indication by the 1998 American College of Cardiology/American Heart Association Task Force on Practice Guidelines, with valve replacement with a mechanical prostheses is classified as a class II or IIa indication.[68] This recommendation is based on a widely held opinion that the risk of accelerated bioprosthetic valve failure mandates the use of mechanical prosthetic valves in hemodialysis patients.

In a study of over 95,000 patients, Byrne and colleagues reported the survival of all Medicare patients with end-stage renal failure in the United States from 1982 to 1987.[130] The average survival of a patient between 55 and 65 years old, from the time dialysis was started, was 52 percent at 3 years and 33 percent at 5 years. This suggests that the life expectancy among these patients is so poor that there is little need for a prosthetic valve that will endure more than a few years in this population.

Lucke and coworkers[131] reviewed their experience with 19 patients on long-term dialysis undergoing valve replacement from 1979 to 1994. Nine patients received bioprosthetic

valves and 10 received mechanical valves. At a mean follow-up of 32 months, no patient required reoperation for bioprosthesis degeneration; however, patients receiving mechanical valves had a higher incidence of thromboembolism and bleeding, leading the authors to conclude that bioprosthetic valve replacement was the preferable choice. Kaplon et al. reviewed 42 patients on chronic preoperative dialysis underwent valve replacement, of which 17 received mechanical valves and 25 received bioprostheses. Survival at 3 and 5 years was 50 and 33 percent after mechanical valve replacement, and 36 and 27 percent after bioprosthetic valve replacement ($p = 0.3$). Four patients with bioprostheses required reoperation: three for allograft endocarditis and one at 10 months for bioprosthesis degeneration. One patient who received a mechanical valve required reoperation. The authors concluded that since the life expectancy of patients on dialysis is limited, bioprosthesis degeneration will be uncommon and therefore, surgeons should not hesitate to implant bioprosthetic valves in these patients.[132] More recently, Brinkman and associates[133] reviewed 72 patients on chronic dialysis undergoing valve replacement. In the 46 patients with reliable long-term (greater than 30 days) follow-up data, significant bleeding or stroke was documented in 17 of 34 patients with a mechanical valve and 1 of 12 patients with a bioprosthetic valve. The type of valve implanted did not influence early and late survival. The authors concluded that the six-fold higher incidence of late bleeding or stroke in patients on dialysis with a mechanical valve requiring warfarin suggested that bioprosthetic valves are the valve substitute of choice in patients on chronic dialysis. Finally, Herzog and colleagues[134] studied dialysis patients hospitalized for heart valve replacement surgery from 1978 to 1998 from the US Renal Data System database. The in-hospital mortality of 5858 dialysis patients (of which 3415 underwent AVR) undergoing valve surgery was 20.7 percent. There was no significant difference in survival related to type of prosthetic valve. The authors concluded that there was no significant difference in survival of dialysis patients after cardiac valve replacement with tissue versus nontissue prosthetic valves.

The above data indicate that valvular replacement in patients undergoing hemodiaylsis has a poor prognosis, and while either prosthesis choice is a viable option, the weight of evidence tends to support use of bioprosthetic valves in these patients.

## Aortic Valve Replacement in Infective Endocarditis

Infective endocarditis is a highly lethal disease in which a microorganism colonizes a site in the heart and produces a variety of manifestations including fever, sepsis, splenomegaly, and embolic events. With aortic valve endocarditis cardiac abnormalities such as congenitally bicuspid, degenerative and rheumatic valve disease create endocardial "jet lesions," which promote seeding by microorganisms. Common microorganism sources include dental extractions, endoscopy, urinary tract infections, chronic intravenous drug, and requirements for long-term, frequently intravenous access with chronic chemotherapy, parenteral nutrition, or hemodialysis.

Greater than 80 percent of native endocarditis cases are due to streptococci (50 percent) and staphylococci (20 percent). The first line of treatment for subacute endocarditis (usually caused by less virulent strains such as *Streptococcus viridans*) is antimicrobial therapy in endocarditis is guided by identification of the infective organism. The much more fulminant cases of acute endocarditis (often caused by *Staphylococcus aureus*) do not respond well to antibiotics and early surgery is almost always recommended if feasible. PVE also has subacute and acute forms and a wide spectrum of organisms can be responsible. In "early" PVE, endocarditis within the first 2 months after surgery, *Staphylococcus epidermidis* is the most frequent organism. Late-onset PVE more closely follows the profile of native valve endocarditis. *Enterococcus faecalis* and *Enterococcus faecium* account for 90 percent of enterococcal endocarditis, usually associated with malignancy or manipulation of the genitourinary or gastrointestinal tracts. Recently, the HACEK group (*Haemophilus, Actinobacillus, Cardiobacterium, Eikenella,* and *Kingella* species) have become important causes of endocarditis. In addition to bacteria, fungi, especially *Candida,* are important causes of endocarditis in patients with prosthetic valves, compromised immune systems, or IV drug abuse.

Indications for surgical intervention in endocarditis include new-onset, unmanageable congestive heart failure or cardiogenic shock secondary to treatable valvular heart disease, with or without an established diagnosis of endocarditis. Prompt intervention should not be delayed in acute infective endocarditis when symptoms of congestive heart failure initiate. Surgery is indicated in patients with life-threatening hemodynamic instability due to surgically treatable valvular heart disease only if the patient's prospects for recovery are reasonable, with satisfactory quality of life after the operation. Surgery is not indicated if complications (such as severe embolic cerebral damage) or comorbid conditions make the prospect of recovery dismal. Additional indications for surgical intervention in the hemodynamically stable patient with documented infective endocarditis include prolonged failure of antimicrobial therapy demonstrated by cultures persistently positive for bacteria, patients with annular or aortic abscesses, pericarditis, fungal and gram-negative endocarditis (antimicrobial therapy is not efficacious), new-onset heart block, evidence of systemic embolism, and vegetation size. Patients with a vegetation diameter >10 mm have a significantly higher incidence of embolization than those with a vegetation diameter <10 mm.[135]

Aortic valve endocarditis is associated with the highest rate of complications, and surgical intervention is most often indicated. Treatment consists of excision of the infected valve, adequate debridement of perivalvular abscesses, and valve replacement. If the endocarditis appears to be confined to the valve leaflets only, prosthetic valve replacement may suffice. In this setting, there are no data supporting superiority

of either bioprosthetic or mechanical valves. Should the disease extend into the annulus with or without abscess formation, then full debridement followed by tissue allograft is required to reduce postoperative reinfection.[136] Involvement of the aortic–mitral continuity may mandate excision of this area and reconstruction with bovine pericardium in addition to valve replacement (Fig. 32-6).[137] If possible, it is recommended that the patient have at least 2 days of broad spectrum intravenous antibiotics to clear microorganisms from the bloodstream.

Operative mortality for infection limited to only the aortic valve leaflets themselves compares to the operative mortality of isolated uninfected AVR; however, mortality is higher in those with aortic root abscesses or PVE.[137] Published results show an operative mortality for native valve endocarditis of less than 10 percent, and for PVE of between 20 and 25 percent.[138,139] David et al. reported on 62 patients undergoing valvular intervention for active endocarditis, and reported an operative mortality rate of zero for native valve endocarditis and 12.5 percent for PVE.[140] Valve replacement in hemodynamically stable patients results in a favorable outcome in over 80 percent of patients; however, a reinfection rate of 1 to 13 percent can be expected.

PVE, as previously discussed, usually involves a clinical course that initiates with antibiotic therapy and ends with valvular replacement. Patients with documented PVE, treated with antibiotic therapy alone, generally experience very poor outcomes. Survival rates without surgery are in the 20 to 30 percent range.[138] Long-term survival of PVE following valve replacement is approximately 60 percent at 10 years,[141] with a significant risk of recurrent endocarditis. Recent use of aortic root homografts as the first option for replacement

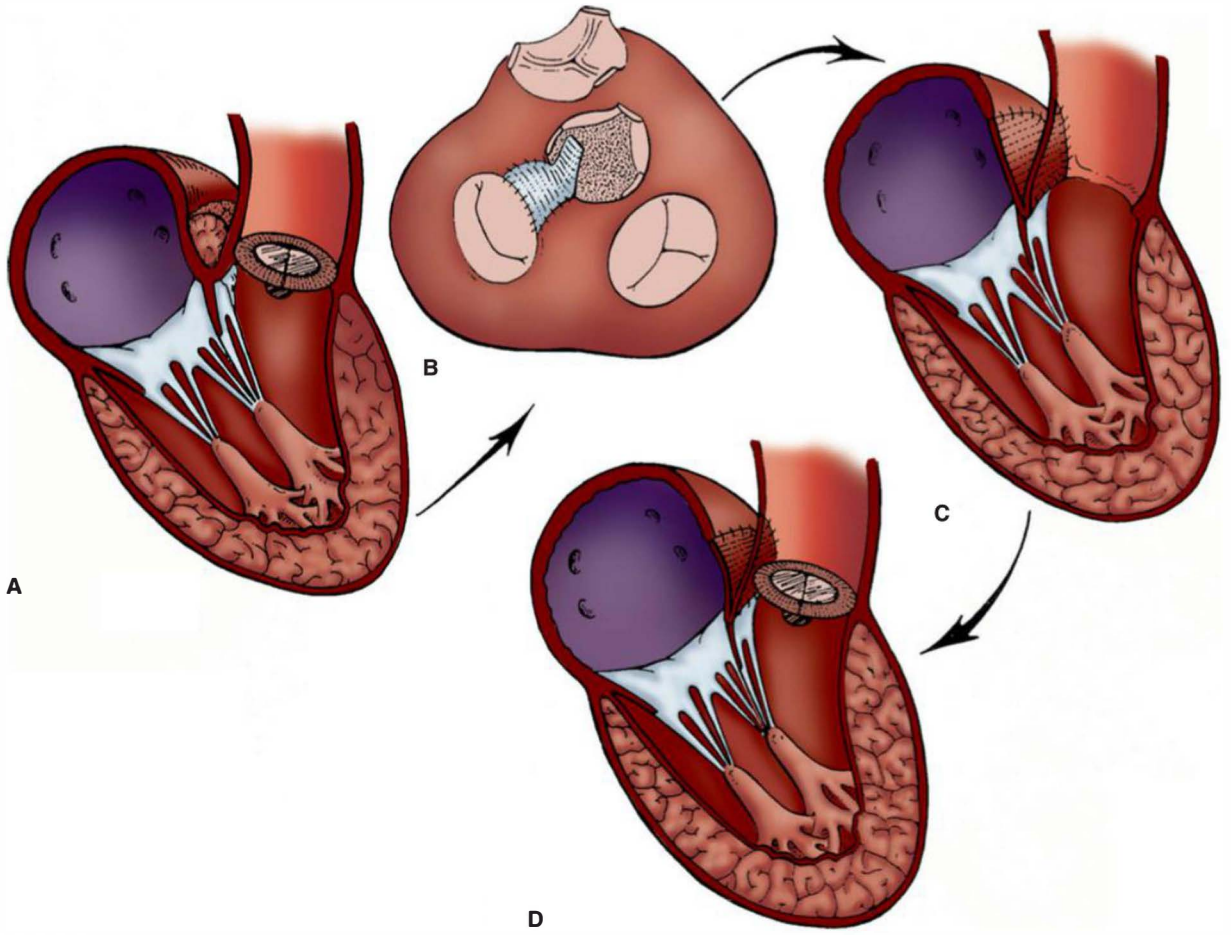

**FIGURE 32-6** Excision of endocardial abscess within fibrous trigone with pericardial patch reconstruction. **A.** Diagram of periprosthetic valvular abscess extending into the fibrous trigone and roof of the left atrium. **B.** Cross-sectional view of the base of the heart with pericardial patch sutured to the fibrous trigone along the mitral annulus, roof of the left atrium, and the aortic root. **C.** Sagittal view of patch reconstructing the aorto-mitral continuity, roof of the left atrium, and the aortic root. **D.** New prosthetic implant inserted. have produced improved both early and late survival, and this has become the preferred choice of valve for PVE.[142]

## Aortic Valve Replacement Following Mediastinal Radiation

Mediastinal radiation has been used to treat numerous types of thoracic malignancies over the years including, but not limited to, Hodgkin and non-Hodgkin lymphomas, thymomas, and breast and lung cancers.[143–147] While radiation therapy has proven to be successful in the management of these malignant processes, particularly Hodgkin lymphoma, it is known to lead to cardiac disease, often times many years, if not decades, following radiation exposure.[145,147] The spectrum of radiation-induced mediastinal disease includes acute and constrictive pericarditis, myocardial fibrosis, proximal CAD, conduction abnormalities, and valvular dysfunction.[143–146] Subsequent valvular dysfunction can be particularly problematic as both left-sided valves as well as the fibrous skeleton of the heart may be involved.[143,144] Importantly, the boundaries of radiation exposure and administered dose of radiation appear to correlate with the incidence and severity of subsequent cardiac valve pathology.[143,147] In their retrospective review conducted at the Cleveland Clinic, Chang and colleagues concluded that patients receiving extensive radiation therapy, such as those with Hodgkin lymphoma, had worse short- and long-term survival after cardiac surgical procedures compared to patients who received fewer fractions of radiation therapy for other malignant diseases (i.e., breast cancer) and particularly when delivered in a tangential fashion as opposed to more central delivery.[143] With respect to the aortic valve, both stenosis and regurgitation may be observed following administration of mediastinal radiation and a high index of suspicion for these pathologic cardiac processes should be maintained for those individuals who receive greater than 3500 cGy.[144] Heidenreich and associates echoed this cautionary advice and advocated routine echocardiographic interrogation for all asymptomatic patients subjected to 3500 cGy or more mediastinal radiation. Importantly, in their retrospective review these same authors noted that the incidence of radiation-induced valve pathology increases over time and in a manner that is independent of patient age.[145] Moreover, they reported that the degenerative process occurs for a period of at least two decades following the initial exposure. In other words, a seemingly normal aortic or mitral valve by echocardiographic criteria early after radiation exposure failed to predict a low risk for future valvular pathology.[145] Hull et al. similarly reported that clinically significant valve dysfunction occurred at a median of 22 years following administration of radiation therapy (range, 6–31 years) with a median dose of approximately 3700 cGy (range, 2200–4400 cGy) in patients treated for Hodgkin's lymphoma. It is fortunate that recent refinements in the therapy used to treat patients with Hodgkin's lymphoma, namely, application of combination chemotherapy/radiation regimens, have reduced radiation dose requirements necessary to achieve successful outcomes.[145] Nevertheless, it is likely that cardiac valve pathology will remain a clinical challenge for both patients and cardiac surgeons alike for the foreseeable future. Accordingly, if AVR is to be performed in patients secondary to radiation-induced disease, the proximal coronary arteries should be assessed for flow-limiting stenoses and bypassed as appropriate. In addition, the operating surgeon should be cognizant of the potential for associated proximal ascending aortic calcification and the potential for difficult aortotomy creation and subsequent closure. Because pericardial disease is the most common manifestation of mediastinal radiation, some authors have advocated routine anterior pericardiectomy at the time of valve substitution so as to avoid future complications.[144] However, routine concomitant pericardiectomy remains controversial and has been selectively performed in some centers.[143] Care should be taken in opening the sternum as the innominate vein may be contracted secondary to mediastinal radiation. Aggressive sternal separation with self-retaining retractors may result in an innominate vein tear or avulsion and profuse bleeding.

## Percutaneous Aortic Valve Replacement

Familiarity with endovascular techniques and the recent development of catheter-based valve substitution products has extended relief to patients with severe symptomatic AS who are deemed poor candidates for traditional AVR.[148–151] The balloon-expandable Edwards SAPIEN valve (Edwards Lifesciences, Irvine, CA) and the self-expanding CoreValve (Medtronic, Minneapolis, MN) (Fig. 32-7) are two transcatheter aortic valve devices that have been approved for use in Europe and are deployed via transfemoral/transapical and transfemoral approaches, respectively. Evaluation of high-risk patients treated with catheter-based transapical AVR in the TRAVERCE (Trans-Apical surgical Delivery of the Cribier–Edwards Aortic Bioprosthesis Clinical Feasibility) investigation revealed a high degree of procedural success (90 percent) as evidenced by correct valve placement, greater than doubling of the aortic valve area, and marked reduction in aortic valve mean gradients.[152] Results from studies evaluating the efficacy of retrograde transfemoral valve insertion are favorable as well and multicenter registries from the United States (REVIVAL II [tRans-catheter EndoVascular Implantation of VALves II] trial) and European Union (REVIVE II [Registry of EndoVascular Implantation of Valves in Europe II]) continue to assess the effectiveness transcatheter AVR via the transfemoral approach in high-risk patients.[148,150,151] A recent prospective study performed by Gotzmann and colleagues assessed hemodynamic results and changes in ventricular function following deployment of the CoreValve via a transfemoral approach.[148] Patient–prosthesis mismatch (indexed aortic valve area $\leq 0.85$ cm$^2$) was observed in approximately 10 percent of the treated patients, a postoperative result not unlike that, and perhaps even more desirable than that observed in patient series treated

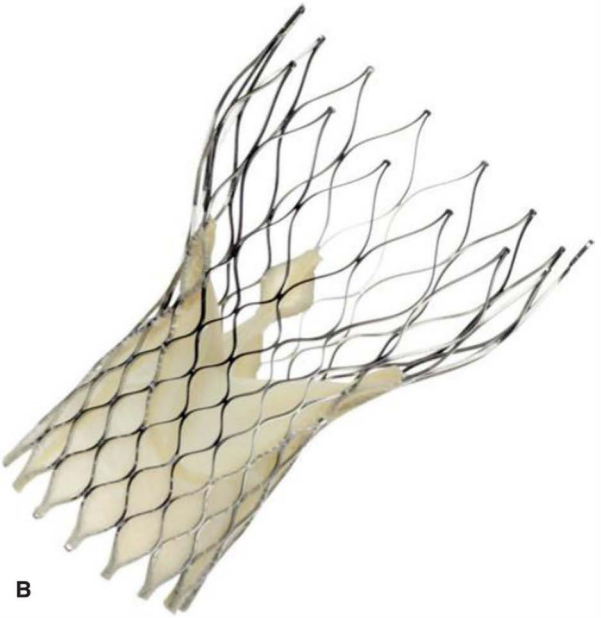

**FIGURE 32-7 A.** Balloon-expandable Edwards SAPIEN valve. (Reproduced with permission from Edwards Lifesciences, Irvine, CA.) **B.** Self-expanding CoreValve. (Reproduced with permission from Medtronic, Minneapolis, MN.)

with conventional AVR.[153,154] Significant decreases in LV mass index were observed 30 days following valve deployment when compared to baseline values and further reductions were noted at 6 months. Significant and substantial reductions in aortic valve peak velocities and mean gradients were noted in the treated patients and their functional status improved markedly. Of importance, a high incidence of paravalvular regurgitation post-valve-deployment appeared to have no untoward effects on ventricular function and dimensions or on overall patient outcomes.[148]

The success of transcatheter AVR hinges upon appropriate patient selection and preoperative evaluation. Inclusion criteria as described by the European Association of Cardio-Thoracic Surgery and European Society of Cardiology include patients with a logistic EuroSCORE or STS score ≥20 or 10 percent, respectively.[155] Clinical considerations for inclusion also include patients with prior mediastinal radiation, prior surgical coronary artery revascularization with patent grafts, marked ascending aortic calcification, severe lung disease, and cirrhosis.[155] Exclusion criteria include patient characteristics pertaining to both vascular and aortic valve anatomy. For instance, transcatheter AVR should be avoided in patients with severely calcified, tortuous, or small iliac arteries and in those patients with severe aortic

angulation, abdominal aortic aneurysms with protruding mural thrombus, or a heavy burden of arch or ascending aortic atheromas. Aortic root and aortic valve annular dimensions require close scrutiny and measurement. Patients with measured annuli <18 mm or >25 mm should not undergo placement of currently available balloon-expandable valves whereas self-expanding prosthesis can be deployed in patients with annuli ≥20 mm and ≤27 mm. Other exclusion criteria include patients with bicuspid aortic valves and those with asymmetric valve calcification as valve deployment may result in incomplete expansion or coronary artery obstruction, respectively.[155] Preoperative assessment should left-heart catheterization, echocardiography, and contrasted computed tomography scans of the entire aorta and vascular circulation to the level of the femoral vessels. These procedures are typically carried out in "hybrid" suites that provide both state-of-the-art fluoroscopic imaging capabilities as well as a setting in which more complicated surgical procedures can be expeditiously carried out in the event that vascular access complications or clinical deterioration is encountered. Potential complications associated with transcatheter AVR include but are not limited to vascular access site injuries (perforation, dissection), coronary artery obstruction, LV apical disruption, significant paravalvular insufficiency, and stroke.[155] Fortunately, this latter complication appears to occur with a frequency of less than 1 percent in a recent investigation.[149]

Irrespective of the transcatheter valve devices selected or the manner in which they are deployed, it appears that this emerging technology is relatively safe and effective in appropriately selected patients. Thus, it appears likely that this technology will be able to be applied to similar patient populations in the United States in the near future, although initial short-term data from the United States PARTNER (Placement of Aortic Transcatheter Valve) trial assessing the effectiveness and safety of the Edwards SAPIEN valve remain to be reported.

## AORTIC VALVE REPLACEMENT BOARD REVIEW QUESTIONS (CHAPTER 32)

1. Which of the following is true regarding embryology and anatomy of the aortic valve?
   A. The free margin of the left coronary cusp is 1.5 times longer than the hinge point.
   B. The aortic valve forms during the 12th week of embryonic development.
   C. Portions of the noncoronary and left coronary cusps are in continuity with the anterior leaflet of the mitral valve.
   D. The annulus is most robust in the region corresponding to the right coronary sinus, located between the two fibrous trigones.
   E. The three valve layers are relatively devoid of elastin, collagen, and glycosaminoglycans.

2. Which of the following is true regarding aortic valve stenosis?
   A. The left ventricular response typically includes profound eccentric myocyte hypertrophy, progressive myocardial fibrosis, and an increase in chamber compliance.
   B. As LV-wall thickness increases, coronary blood flow is impaired during late systole and flow reserve is reduced.
   C. Severe concentric and septal hypertrophy may not be correctable with valve replacement.
   D. Valve replacement results in complete and rapid (less than 1 month) normalization of systolic and diastolic ventricular function.
   E. Bicuspid valve occurs in 15 percent of the population.

3. Which is true regarding aortic insufficiency?
   A. Isolated insufficiency is usually due to structural abnormalities of the valve causing leaflet elongation and prolapse.
   B. Most patients with acute severe insufficiency can be managed with delayed elective operation.
   C. The enlarging ventricular chamber increases wall stress and ventricular hypertrophy, resulting in an increased diameter to wall-thickness ratio.
   D. Chronic insufficiency causes eccentric fibrosis, which decreases regional stiffness and enhances diastolic relaxation.
   E. Chronic insufficiency is associated with a narrowed pulse pressure and preserved diastolic coronary perfusion.

4. Which is true regarding clinical presentation of aortic valve disease?
   A. Severe stenosis secondary to bicuspid valve usually presents during the seventh decade of life.
   B. Syncope is the most common initial presenting symptom in severe stenosis.
   C. Patients with severe stenosis and angina have a worse prognosis compared to patients with severe stenosis and congestive heart failure.
   D. Patients with severe insufficiency are prone to sudden cardiac death.
   E. Aortic insufficiency has an insidious onset characterized by the gradual development of congestive heart failure and fatigue.

5. Which is true regarding aortic valve replacement?
   A. Enlargement of the posterior annulus is effective therapy for patient–prosthesis mismatch.
   B. Full aortic root replacement with a Medtronic free-style bioprosthesis has been shown to have nearly 100 percent freedom from aortic insufficiency and reoperation at 8 years.
   C. Placement of everting annular sutures generally enables placement of the largest possible prosthesis.
   D. Postoperative patient–prosthesis mismatch is associated with statistically significant reductions in short- and long-term survival.
   E. Homograft aortic valve replacement is associated with early rapid calcification and structural deterioration.

## ANSWERS

1. **Answer: C.** Portions of the noncoronary and left coronary cusps are in continuity with the anterior leaflet of the mitral valve, also known as aorto-mitral continuity.
2. **Answer: C.** Severe concentric and septal hypertrophy may cause intracavitary gradients that are not correctable with valve replacement.
3. **Answer: A.** Isolated aortic insufficiency is usually a consequence of structural abnormalities of the valve, causing leaflet elongation and prolapse. This can occur in myxomatous degeneration and connective tissue disorders.
4. **Answer: E.** Aortic insufficiency has an insidious onset characterized by the gradual development of congestive heart failure and fatigue. Angina and syncope are rare.
5. **Answer: B.** In addition to providing excellent postoperative hemodynamics, full aortic root replacement with the Medtronic free-style bioprosthesis has been shown to have nearly 100 percent freedom from aortic insufficiency and reoperation at 8 years.

# Aortic Root Replacement

*Kaushik Mandal*
*Duke E. Cameron*

## KEY CONCEPTS

- Epidemiology
  - Aortic aneurysms were the 15th most common cause of death in the United States in the year 2000. Among patients who die of thoracic aortic aneurysms (TAAs), rupture is the cause of death in about 80 percent of cases. Approximately 50 percent of thoracic aneurysms involve the root and the ascending aorta. The estimated growth rate for TAAs has been calculated to be 1.2 to 4.2 mm/year. Aneurysms that are larger than 6 cm can be associated with a yearly rate of rupture or dissection of at least 6.9 percent and a death rate of 11.8 percent.
- Pathophysiology
  - Annuloaortic ectasia is a term used to describe an increase in diameter of the aortic annulus coupled with an increase in the diameter of the aortic root. This type of situation is seen in patients with Marfan syndrome, Ehlers–Danlos syndrome, Loeys–Deitz syndrome, osteogenesis imperfecta, and pseudoxanthoma elasticum. Annuloaortic ectasia may have familial origins or may be idiopathic. Recently, a significant body of research has focused on the involvement of endogenous extracellular matrix-degrading enzymes in aneurysms and aortic remodeling. Of greatest interest are the matrix metalloproteinases (MMPs), particularly those of the gelatinase class (MMP-2, MMP-9). Similarly ARB2 receptor blockade with Losartan has shown to slow the dilatation of aorta in animal model studies. Another important cause of aortic root destruction is acute infective endocarditis with aggressive organisms such as *Staphylococcus aureus*. A central common theme in the development of aortic root aneurysms is cystic medial degeneration, in which gradual disruption of the media of the aorta occurs, with the creation of small acellular spaces within it. This process weakens the aortic wall, and a slow remodeling of the aortic root and ascending aorta results in aneurysm formation.
- Clinical features
  - Most patients with aortic root pathology are asymptomatic, with the exception of patients who present with endocarditis (sepsis, congestive heart failure) or aortic root destruction secondary to acute type A aortic dissection (severe chest pains, asymmetric pulses, congestive heart failure). The age range of presentation is very broad (twenties to eighties) and is dependent on the underlying pathology. Certain patients will have characteristic stigmata of connective tissue diseases such as Marfan syndrome.
- Diagnostics
  - The workup for candidates for aortic root replacement includes echocardiography to estimate ventricular function and assess for the possibility of aortic valve preservation. Coronary catheterization is usually necessary to rule out coronary artery disease. Thin-slice computed tomography (CT) or magnetic resonance imaging (MRI) scanning will provide the necessary information about the anatomy of the aneurysm. A careful oral examination or dental consultation is very important to prevent postoperative prosthetic valve infection.
- Treatment
  - Aortic root replacement options include composite valve-graft, separate valve-graft, xenograft tissue, homograft, pulmonary autograft (Ross procedure), and valve-sparing aortic root replacement. The decision to use each one of these options is dependent on patient age and valve preference, comorbid conditions, the condition of the native aortic valve, and contraindications to the use of anticoagulants.
- Outcomes
  - Operative (30-day) mortality runs in the range of 0 to 10 percent. Reoperation for mediastinal hemorrhage should be required in less than 10 percent of cases. Complete heart block requiring pacemaker insertion occurs in about 1 to 2 percent in most series. Stroke occurs in approximately 1 to 4 percent of these patients. Approximately 30 percent of patients who present for aortic root replacement are candidates for a valve-sparing procedure that offers improved freedom from bleeding and thromboembolic complications and obviates the need for oral anticoagulation.

## BACKGROUND

The first thoracic aortic replacements were performed with homograft tissue primarily in the descending thoracic aorta. Continuing efforts at developing an artificial fabric graft for use for aortic replacement, culminated with Michael DeBakey's discovery of Dacron.[1] During the late 1950s, the Houston group led by Michael DeBakey systematically developed operations for resection and graft replacement of the ascending aorta, followed by the descending and thoracoabdominal aorta. In 1968, Bentall and DeBono published a landmark article on replacement of the entire aortic root with anastomoses of the coronary ostia to the replacement graft.[2] The description of this technique included side-to-side anastomoses of the coronary arteries to the graft. The aneurysm sac then was closed completely around the graft. A common complication of this operation was pseudoaneurysmal development at the level of the coronary ostia, presumably caused by the tension placed on the coronary anastomoses. A subsequent modification of this technique by Kouchoukos and coworkers[3] included complete excision of the aneurysm and aortic root, leaving both coronary arteries suspended by only a small "button-shaped" circular portion of aorta that then would be anastomosed directly into a hole created in the side of the Dacron graft, thus eliminating pseudoaneurysm formation. An extended ascending aortic replacement was described by Wheat and associates, effectively excluding most of the ascending aorta but leaving the coronary arteries attached to the remaining aortic root tissue in continuity.[4]

In 1979, acting on the observation that many patients presenting for aortic root replacement have normal aortic valve morphology, Sir Magdi Yacoub and colleagues at Harefield Hospital in the United Kingdom developed a strategy for aortic root replacement in which the aortic valve was preserved.[5] In 1988, Tirone David introduced a different technique for valve-sparing aortic root replacement.[6]

Interest in homograft aortic root replacement began in the 1950s. At that time, Norman Shumway and colleagues at Stanford University were experimenting with excision of the right ventricular outflow tract, the pulmonary valve, and the proximal portions of the pulmonary artery in continuity in dogs and translocating this to the aortic root, with subsequent reconstruction of the pulmonary artery with homograft or tube graft material.[7] The operation in this iteration ultimately would be doomed to failure because of right ventricular failure resulting from the lack of a pulmonary valve, but Donald Ross, building on that experience, later performed the first pulmonary autograft aortic root replacements in humans.[8]

## DEVELOPMENTAL ANATOMY

The aortic root and the ascending aorta develop as part of a common truncus arteriosus that partitions itself into the ascending aorta and the aortic root and the pulmonary artery at approximately the fifth and sixth weeks of development. The aortic root is a tripartite structure owing to the presence of coronary sinuses. The aortic valve proper has no true fibrous annulus, although surgeons use the term *aortic annulus* to describe the junction of the aorta and the ventricle. The noncoronary sinus of the aortic valve tends to be the largest of the three sinuses, and therefore the size of the aortic valve leaflets reflects this, with the noncoronary leaflet generally being the largest. The length of the distance from the basal attachment of each aortic valve leaflet to the aorta is approximately 1.5 times the length of the free margin of the leaflet (Fig. 33-1). The commissures of each of the aortic valves extend right to or just below the sinotubular junction that marks the anatomic ridge between the end of the aortic root and the beginning of the ascending aorta. In general, the sinotubular ridge is approximately 10 to 15 percent smaller in diameter than the aortic annulus (Fig. 33-1). Anatomic disease states that cause dilatation of the sinotubular junction or dilatation of the aortic annulus will cause insufficiency of the aortic valve. There is an aortic–mitral continuity, which is a fibrous tissue attachment between the aorta and the mitral valves that constitutes approximately 55 percent of the circumference of the aortic root. The left side of the aortic root toward the pulmonary artery is attached to the ventricular muscle, corresponding to approximately 45 percent of the circumference.

## EPIDEMIOLOGY

The exact extent of occurrence of thoracic aortic aneurysms (TAAs) is unknown. Bickerstaff and associates[9] found the prevalence of TAAs to be 5.9 per 100,000 per year in the Rochester, MN, area. Among a total of 72 patients with TAAs studied by Bickerstaff and colleagues, 51 percent, or 37 of the aneurysms in those patients, involved

the ascending aorta, 8 (11 percent) the aortic arch, and 27 (38 percent) the descending thoracic aorta.

According to the National Center for Health Statistics, aortic aneurysms (AAs) were the 15th most common cause of death in the United States in the year 2000; approximately 0.6 percent of all females and 1.1 percent of all males die of aortic aneurysmal disease. TAA deaths occur in about 0.7 per 100,000 population per year.[10] Among patients who die of TAAs, rupture is the cause of death in about 80 percent of cases.

The estimated growth rate for TAAs has been calculated to be 1.2 to 4.2 mm/year, and enlargement accelerates as an aneurysm gets larger.[11] Risk factors for accelerated growth include the presence of dissection in the enlarged segment, synchronous arch or abdominal AA, smoking, no β-blocker therapy, renal failure, and diastolic hypertension. Rupture is much more likely to occur when the aneurysm exceeds 5 cm in diameter, and the risk of rupture increases as the aneurysm increases in size. Aneurysms larger than 6 cm can be associated with a yearly rate of rupture or dissection of at least 6.9 percent and a death rate of 11.8 percent.[12]

## PATHOPHYSIOLOGY

*Annuloaortic ectasia* is a term used to describe an increase in the diameter of the aortic annulus coupled with an increase in the diameter of the aortic root. This ectasia tends to occur along the fibrous tissue of the ventricle, with the ventricular muscular portion of the aortic root generally preserved. This type of situation is seen in patients with Marfan syndrome (characterized by defect in the fibrilin gene), Ehlers–Danlos syndrome (characterized by a defect in type 3 collagen synthesis), Loeys–Dietz syndrome (characterized by a defect in Transforming Growth Factor beta gene), osteogenesis imperfecta, and pseudoxanthoma elasticum. It may have other familial origins or may be idiopathic. In these syndromes, the aortic sinuses become thinner and dilated and the sinotubular junction increases in diameter. When this happens, the aortic valve leaflets are not allowed to coapt properly because of separation of the commissures. These patients develop central jets of aortic insufficiency on echocardiographic assessment. Degenerative diseases of the aorta may cause dilatation of the ascending aorta and aortic sinuses with minimal or no dilatation of the aortic annulus. The aortic root also may be destroyed in the setting of acute or chronic aortic dissection and other congenital syndromes, such as those associated with bicuspid aortic valves. Recently, a significant body of research has focused on the involvement of endogenous extracellular matrix degrading enzymes in the involvement of aneurysms and aortic remodeling. Of greatest interest are the matrix metalloproteinases (MMPs), particularly those of the gelatinase class (MMP-2, MMP-9).[13,14] Another important cause of aortic root destruction is acute infective endocarditis with aggressive organisms such as *Staphylococcus aureus*.

A central common theme in the development of aortic root aneurysms is a condition referred to as cystic medial degeneration or simply medial degeneration. Histologically, the aorta is made up of three layers. The adventitia is composed primarily of a collagen-rich network. The tunica media, or media, is composed of alternating layers of vascular smooth muscle and elastin. Each successive pairing of smooth muscle cells and elastin is referred to as a lamellar unit. In humans, the media of the aortic root is composed of approximately 50 lamellar units. The third layer of the aorta is referred to as the intima and is composed of a single layer of epithelial cells. In many cases of AA, one sees gradual disruption of the media of the aorta, with the creation of small acellular spaces within it. This process of medial degeneration results ultimately in weakening of the aortic wall and inability to sustain the normal shear stresses associated with systole. As a result, a slow remodeling of the aortic root and ascending aorta occurs, leading to aneurysm formation.

## CLINICAL PRESENTATION AND DIAGNOSTIC MODALITIES

Patients present for aortic root replacement in a number of circumstances (see the decision-making flowchart; Fig. 33-2). The most acute circumstance is a patient with a Stanford type A aortic dissection in whom the aortic root is virtually destroyed by the proximal extent of the dissection. The condition of these patients constitutes a surgical emergency, and as a result, aortic root replacement in these circumstances is associated with more morbidity and a higher mortality than is standard aortic root replacement. A second acute situation occurs with infective endocarditis. The most common situation in which patients present for aortic root replacement is an aortic root aneurysm. The age range of presentation is wide and starts in the 20s and 30s in patients with hereditary connective tissue disorders and extends into the 70s and even 80s in those with degenerative aneurysms. Other than a family history of AAs and connective tissue disorders, risk factors for AAs include hypertension and atherosclerosis. Patients with isolated aortic root aneurysms are usually asymptomatic. Those conditions are identified as a result of a workup for another disease process, such as a respiratory tract infection, that results in a chest x-ray. The chest x-ray may identify an abnormality in the mediastinum, resulting in a computed tomography (CT) scan or a magnetic resonance imaging (MRI) scan that illustrates the aortic root aneurysm. Alternatively, other patients with AAs have significant aortic valve pathology, such as stenosis or insufficiency. Symptoms from these conditions result in referral to a physician. An echocardiogram is performed and shows evidence of aortic stenosis or insufficiency, and often a dilated aortic root is identified. This often leads to a further imaging study, such as a CT scan or an MRI scan, which shows the aortic root aneurysm.

The workup in patients with an aortic root aneurysm involves a careful history and physical examination, assessing for a history of bleeding problems and a history of significant dental work. In addition, a family history of AA

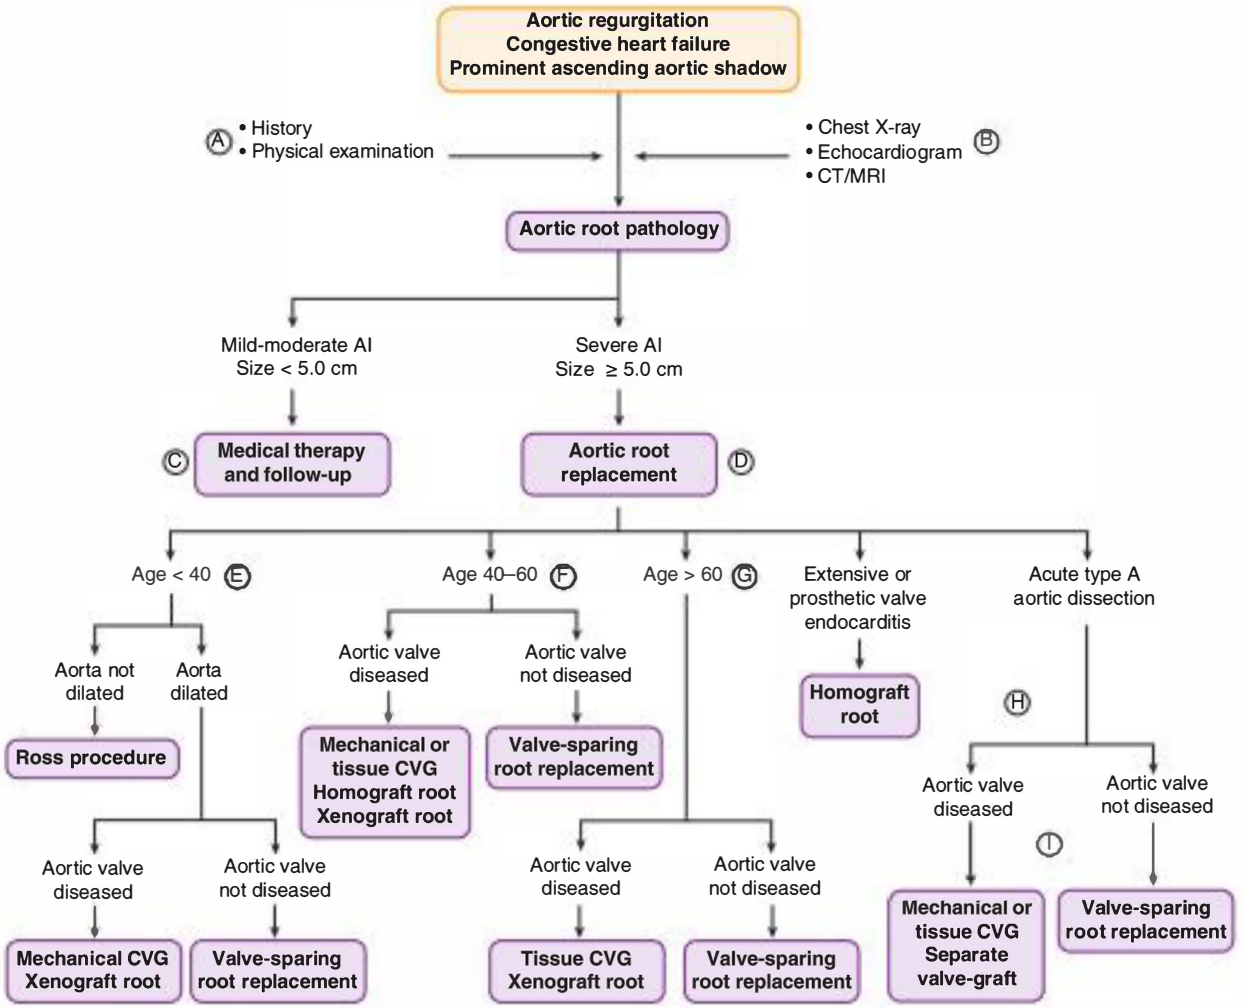

**FIGURE 33-2** Decision-making flowchart: Aortic root replacement.

should be elicited. The physical examination is generally unremarkable apart from the features of aortic insufficiency and aortic stenosis. Patients with Marfan syndrome have a very characteristic appearance. They tend to be tall and thin, with joint laxity, pectus excavatum, and very characteristic facial features. After physical examination, patients should have standard blood work and be crossed and typed for 4 to 6 units of red blood cells. Clotting studies should be performed. The electrocardiogram shows no abnormalities specific to the aortic root aneurysm. Chest x-ray often reveals a prominent right mediastinal border, which represents an outpouching of the aortic root and the ascending aorta into the right chest. Transthoracic echocardiography is valuable in showing features of aortic stenosis and aortic insufficiency in addition to allowing assessment of the potential for valve preservation. The most useful test for the evaluation of aortic root aneurysms is a contrast CT scan or MRI, especially scans with three-dimensional reconstructions; this allows precise assessment of the aortic root and its dimensions (Fig. 33-3). Females older than 40 years and males older than 35 years with coronary risk factors should undergo coronary angiography to rule out the presence of coronary artery disease before surgery. In addition, patients with significant neck bruits should have carotid vascular studies and those with a substantial history of smoking should have pulmonary function tests. Finally, a dental examination is critical whenever a prosthetic valve replacement is considered in a patient since bacterial seeding from dental disease is a very important cause of prosthetic valve endocarditis (PVE) and graft infections.

## MEDICAL THERAPY

At the present time, there is no medical therapy for aortic root dilatation that directly addresses the underlying etiology. Some treatment strategies have focused on the use of broad-spectrum MMP inhibitors to reduce or prevent aneurysm

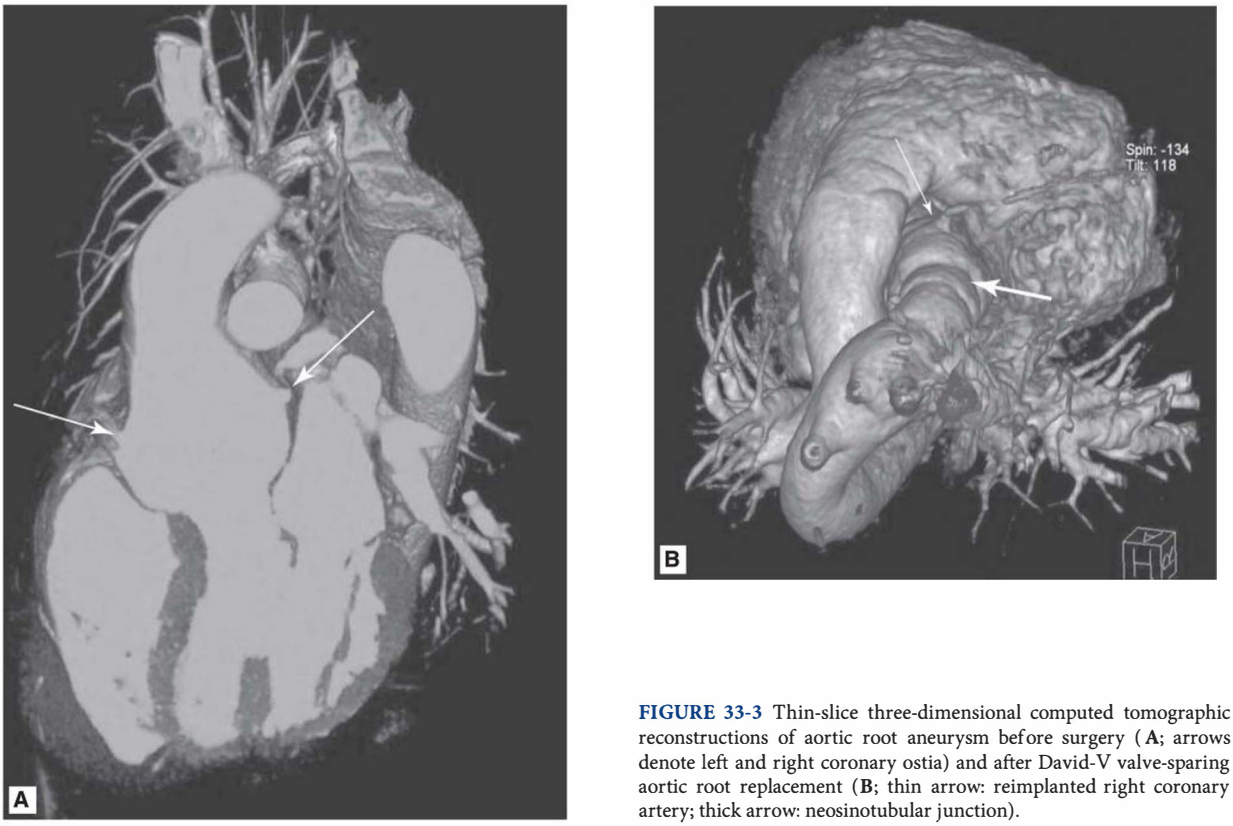

**FIGURE 33-3** Thin-slice three-dimensional computed tomographic reconstructions of aortic root aneurysm before surgery (**A**; arrows denote left and right coronary ostia) and after David-V valve-sparing aortic root replacement (**B**; thin arrow: reimplanted right coronary artery; thick arrow: neosinotubular junction).

expansion. Thompson and Baxter gave doxycycline 100 mg twice a day for 7 days to five patients before abdominal AA repair, and aneurysm biopsy showed a three-fold reduction in MMP-2 and a four-fold reduction in MMP-9 expression compared with nontreated controls in whom those two enzymes were expressed abundantly.[15] After this, a multi-institutional phase II prospective randomized trial was undertaken to assess the safety and potential efficacy of long-term doxycycline administration in 36 patients. Thirty-three patients completed the study, and significant treatment-related side effects occurred in five, or 13.9 percent, of those patients. There was no significant increase in aneurysm size at 6 months, and plasma MMP-9 levels dropped so that only 21 percent of the patients in the drug arm had MMP-9 that was considered to be elevated compared with 47 percent in the control arm.[16] Recent work from our institution has similarly suggested a role for ARB2 blocker Losartan, in slowing the growth of thoracic aneurysms associated with Loeys–Dietz Syndrome.[17] Hence, at present, the mainstays of management of aortic root aneurysms are judicious hypertension control using a combination of β-blockers and ARB2 receptor blockers in conjunction with regular follow-up with CT scans and transthoracic echocardiography to assess for interval changes in aortic diameter and follow the characteristics of the aortic valve.

## INDICATIONS FOR SURGERY

Generally, resection of an aortic root aneurysm is indicated in patients in whom the aortic root diameter exceeds 5 to 5.5 or becomes twice the size of a comparable normal aortic segment.[11] In addition, a patient with an aortic root aneurysm that is seen to grow more than 0.5 cm in a 6-month period also should be considered for operation. Some latitude is given for patients with connective tissue disorders in whom it is known that the aorta is inherently weak and more susceptible to rapid dilatation, especially in patients with Loeys–Dietz syndrome (ascending aortic diameter cutoff 4 cm), those with bicuspid aortic valve (ascending aortic diameter cutoff 4.5 cm), and those with Marfan (ascending aortic diameter cutoff 5 cm). The clinical situation often also arises when patients have significant aortic valve pathology in association with an AA that does not quite meet the size criteria for resection. In these circumstances, aortic root replacement is indicated, since isolated replacement of the aortic valve in patients with a large aortic root and ascending aorta can pose technical difficulties in terms of closing the aorta after the aortic valve procedure and may predispose those patients to aortic dissections. In addition, a complicated redo operation for aortic root replacement may be necessary, since the ascending

aorta continues to dilate. As was stated earlier, aortic root replacement occasionally is indicated in patients with type A aortic dissections with destruction of the aortic root and also in younger patients with significant aortic valve pathology who have a normal aortic root and ascending aorta and who are undergoing homograft root replacement or a Ross procedure to benefit from the increased durability of the aortic valve associated with this operation. Finally, severe aortic valve endocarditis with abscess or PVE may be best treated with homograft aortic root replacement.

# SURGICAL THERAPY

## Conduct of the Operation

The patient is placed in the supine position under general anesthesia. The chest, abdomen, perineum, and lower extremities are prepped and draped in sterile fashion. Standard median sternotomy and exposure of the heart are performed. The orientation of the aortic root is visualized more easily if only the right side of the pericardium is tacked upward. This rotates the heart counterclockwise and allows the apex of the heart to sink into the left chest, thus improving the exposure of the aortic root. Arterial and venous cannulation is undertaken, and appropriate connections are made to the pump oxygenator. If the patient has no significant aortic insufficiency, an antegrade cardioplegia tack is placed, and in all cases a retrograde cardioplegia cannula also is placed. When everything is in readiness for the initiation of cardiopulmonary bypass, careful dissection is undertaken to separate as much of the aortic root from the pulmonary artery and right ventricular outflow tract as possible. Care must be taken in dissecting anteriorly to avoid injury to the right coronary artery. A careful dissection at this point can result in significant exposure of the aortic root and therefore decrease the amount of time needed to perform the aortic root replacement when the aorta is cross-clamped. After confirmation of an activated clotting time (ACT) longer than 400 s, cardiopulmonary bypass is performed and the aorta is cross-clamped. Whenever possible, the heart should be arrested with antegrade cardioplegia to promote better and faster distribution of the cardioplegia. A switch to retrograde cold blood cardioplegia may be considered especially in the presence of significant aortic regurgitation. The authors give intermittent shots of 250 mL every 20 min during the cross-clamp period. This is supplemented with a cold saline-infused cooling jacket placed around the left ventricle. A right superior pulmonary vein vent is placed to keep the heart decompressed.

The ascending aorta is transected approximately 3 to 4 cm above the right coronary ostium. The aortic valve is inspected at this point, and if the situation is appropriate for valve preservation, the valve is not excised. If the valve is diseased so that its successful preservation is not possible, it is excised and debridement of the annulus is carried out if necessary. At this point, both the left and the right coronary buttons are dissected free, taking care not to mobilize them significantly. Significant mobilization may result in disorientation and kinking of the button after anastomosis to the Dacron graft. Specific techniques and choices for aortic root replacement are discussed below.

Systemic rewarming is begun at an appropriate point in the implantation procedure to avoid imposing extra time waiting for the patient to reach normothermia before separation from cardiopulmonary bypass. After root replacement, the vent is removed, and it is useful to give the final shot of cardioplegia antegrade to inspect for significant bleeding points that can be repaired before removal of the cross-clamp and also as an initial test of valve competence. The cross-clamp is removed with the patient placed in the Trendelenburg position and with an ascending aortic vent on. Ventricular and atrial pacing wires are placed, and mechanical ventilation is resumed. De-airing maneuvers such as lung hyperinflation, side-to-side shaking of the chest, and manual agitation of the heart are performed with the heart partially ejecting. Transesophageal echocardiography is very helpful in the assessment of de-airing and also in the interrogation of the valve for correct leaflet function. The patient is weaned from bypass at a systemic temperature of 36.5 to 37°C with good ventilation parameters. Protamine is given slowly, and the patient is decannulated. Meticulous hemostasis is obtained, a midline mediastinal drain (36F thoracostomy tube) is placed, and the patient is closed in the standard fashion.

## Aortic Root Replacement: Choices and Results

### COMPOSITE VALVE-GRAFT

The current gold standard for aortic root replacement is the composite valve-graft replacement. Typically this consists of a mechanical valve that is annealed to a double-velour woven Dacron graft at the factory. The most commonly used version is the St. Jude composite valve-graft, although other brands are available. The operation consists of removal of the aortic root in its entirety except for the coronary ostia that are left surrounded by a small circular rim of native aorta. The aortic valve also is excised. After appropriate sizing, pledgeted horizontal mattress nonabsorbable sutures are placed across the annulus in everting fashion (i.e., from aorta to ventricle) and are placed across the sewing ring of the composite valve-graft. The composite valve-graft is seated, and the sutures are tied and cut. For an extra measure of hemostasis, it is useful to suture the remaining rim of the aortic root directly to the sewing ring of the composite valve-graft in running fashion with 3-0 polypropylene sutures. Small holes are made just above the valve in the graft with ophthalmic cautery to allow suture implantation of the right and left coronary buttons. The authors use a small amount of albumin–glutaraldehyde biological glue to seal the interstices of these suture lines to aid in achieving hemostasis, but with the understanding that this step is not a substitute for meticulous surgical technique. A distal anastomosis of the Dacron graft to the ascending

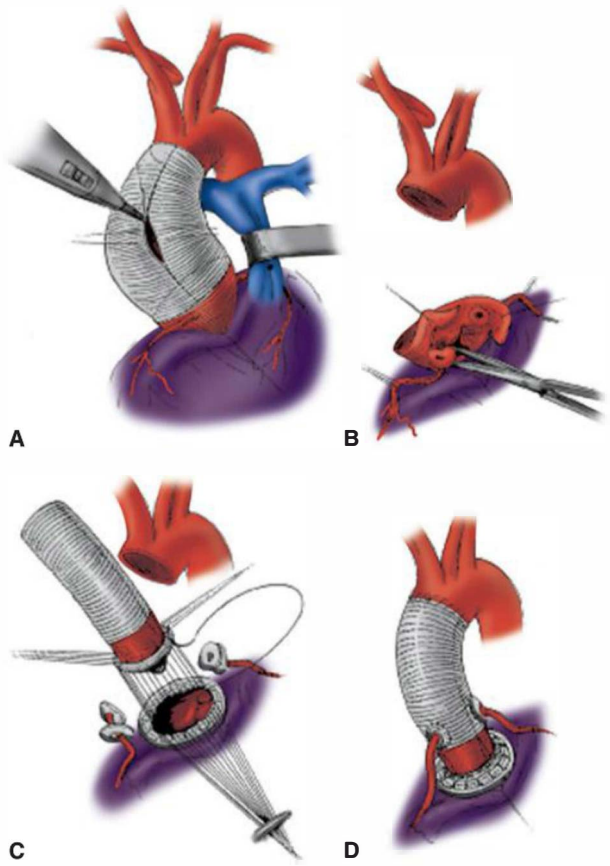

**FIGURE 33-4** Insertion of a composite graft with the button technique. The aorta is opened vertically (**A**), and the coronary ostia are mobilized sufficiently (**B**) before the valve is seated (**C**). The coronary buttons are sewn to the graft (**D**) to complete the repair. (Reproduced with permission from Svensson LG, Crawford ES. Aortic dissection and aortic aneurysm surgery: Clinical observations, experimental investigations, and statistical analyses: Part III. *Curr Probl Surg* 1993;30:1–72. Copyright Elsevier.)

aorta then is performed (Fig. 33-4). In the operation originally described by Bentall and Debono in 1968,[2] the aortic root was not excised and the coronary ostia were sewn side to side to the Dacron graft. Subsequently, Kouchoukos and coworkers excised the native aorta, leaving the coronary ostia surrounded by a small circular rim of native aorta ("Carrel buttons") for direct end-to-side reimplantation.[3] This constitutes the standard operation performed today. It is therefore not academically appropriate to refer to the latter procedure simply as a Bentall operation; instead, it is a modification of that operation.

Younger individuals may opt for a replacement of a composite graft containing a mechanical valve, accepting the potential complications associated with warfarin administration. In older patients (i.e., those above 65–70 years of age) a composite graft consisting of a stented bioprosthetic valve sewn to the Dacron graft by the surgeon at the time of operation may be used. Although these valves are not commercially available, the surgeon can select the appropriate bioprosthetic valve by sizing the annulus after the native valve is excised and then suture it to an appropriately selected Dacron graft. The operation then proceeds as for a composite mechanical valve graft.

During redo aortic root replacements, the tissues around the aortic root, especially posteriorly, can be very difficult to dissect; therefore, mobilization of the coronary artery may be difficult or dangerous. The Cabrol technique[18] of coronary reimplantation involves the placement of 8- or 10-mm tube grafts to each coronary ostium with a side-to-side connection to the main aortic graft (Fig. 33-5). This procedure can be complicated by kinking of the right or left limb of the side graft if it is not oriented correctly in addition to the long-term risk of right coronary artery occlusion. An alternative approach involves direct reimplantation of the right coronary button (which almost always can be mobilized sufficiently) and reimplantation of the left coronary artery with an interposition graft between the aortic graft and the left coronary ostium.

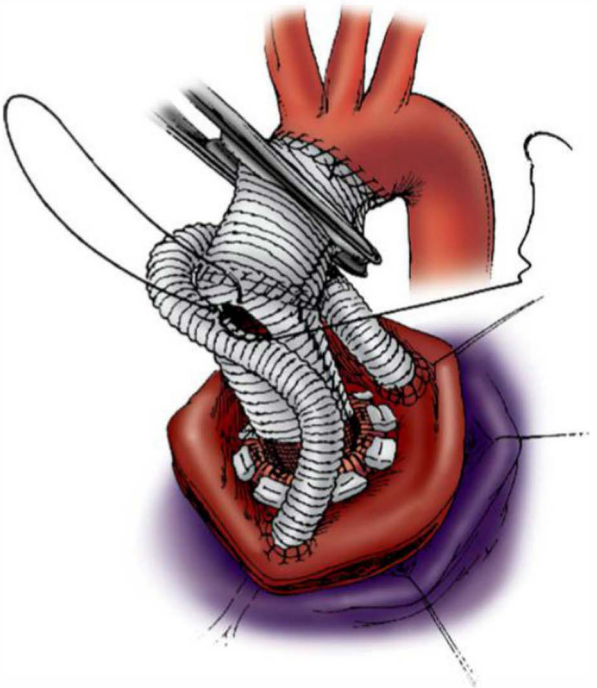

**FIGURE 33-5** Composite valve-graft insertion with the Cabrol technique. The tube graft to the left main ostium is brought behind the composite graft, and the composite graft is sutured to the aortic arch or to the graft that has been used for arch replacement. Finally, the coronary interposition graft is sutured to the right coronary artery ostium and the anastomosis (side-to-side) is completed. (Reproduced with permission from Svensson LG, Crawford ES. Aortic dissection and aortic aneurysm surgery: Clinical observations, experimental investigations, and statistical analyses: Part III. *Curr Probl Surg* 1993;30:1–72. Copyright Elsevier.)

The results of composite valve-graft aortic root replacement operations are generally very good but are dependent on the indication for operation. Gott and associates reviewed the extensive experience at Johns Hopkins with aortic root replacement in Marfan syndrome patients over a 24-year period.[19] Two hundred thirty-five Marfan patients underwent elective aortic root replacement with no 30-day mortality. The actuarial freedom from thromboembolism, endocarditis, and reoperation on the residual aorta 20 years postoperatively was 93 percent, 90 percent, and 74 percent, respectively. Lai and associates reviewed the Stanford experience with composite valve-graft (CVG) replacement for acute type A aortic dissection.[20] Thirty-day, 1-year, and 6-year survival estimates of 86 ± 8, 81 ± 9, and 65 ± 16 percent were seen with composite valve-graft replacement, with a 6-year freedom from reoperation of 100 percent. Ehrlich and coworkers[21] reported on 84 patients older than 65 years of age (median age was 74 years with a range of 66 to 89 years) who underwent CVG aortic root replacement over an 11-year period. Hospital mortality was 8.3 percent (7 of 84), with 16 late deaths (19 percent) noted during a median follow-up of 3.2 years (range 0 to 10 years). The authors concluded that composite valve-graft replacement in elderly patients results in low operative mortality, has excellent long-term survival, and averts fatal aneurysm rupture even in that higher-risk population.

## THE COMPOSITE VALVE-GRAFT VERSUS SEPARATE VALVE-GRAFT CONTROVERSY

In many cases an acceptable alternative to full CVG aortic root replacement is ascending aortic replacement starting at the sinotubular junction in association with separate aortic valve replacement [separate valve-graft (SVG)], leaving an intervening segment of the patient's own aortic root from which the coronary ostia originate. The SVG procedure is less technically demanding and is useful when the sinotubular junction is not effaced and the aortic root is not dilated. It is useful in elderly patients in whom a shorter cross-clamp time may limit morbidity, especially those with acute type A without significant annuloaortic ectasia. A relatively common problem is significant ascending aortic dilatation associated with aortic valve replacement for a bicuspid aortic valve. It is well known that patients with bicuspid aortic valves are predisposed to the development of ascending and root aneurysm. The cause is multifactorial and includes hemodynamic factors and heredity.[22]

McCready and associates[23] observed an approximately 15 percent incidence of significant root dilatation an average of 6.5 years after the SVG procedure. Houel and coworkers[24] found mortality rates of 7.7 percent with CVG versus 11 percent with SVG ($p$ = not significant). Actuarial survival at 10 years postoperatively in these groups was 77.7 ± 5.6 versus 75.8 ± 6.9 percent ($p$ = not significant). However, freedom from late complications of the ascending aorta was significantly different (97.3 ± 1.9 percent CVG versus 68.3 ± 9.0 percent SVG at 10 years postoperatively). The SVG technique was identified as a risk factor for late complications of the ascending aorta by multivariate analysis ($p = 0.01$; odds ratio 9). In light of these data, an aggressive approach to CVG replacement in this population is recommended in patients with acceptable risk.[25] When the sinotubular junction and aortic root are intact so that SVG is considered appropriate, the procedure first described by Wheat and associates[4] may be useful to maximize exclusion of as much native aortic root tissue as possible without incurring the extra technical challenge of a full CVG implantation. The decision to pursue CVG replacement to exclude all potentially diseased aortic root tissue should be tempered by an increased operative mortality rate compared with an isolated aortic valve replacement. The SVG technique may provide a reasonable compromise between these two procedural extremes, especially if concomitant procedures must be performed in the same setting; however, there is a risk of aneurysmal dilatation of the intervening aorta over time.

## STENTLESS VALVE AS AN ALTERNATIVE FOR AORTIC ROOT REPLACEMENT

The Freestyle aortic root bioprosthesis (Medtronic, Inc., Minneapolis, MN) is a stentless porcine aortic root prepared with low-pressure and zero-pressure fixation processes and α-aminooleic acid leaflet anticalcification treatment, with the aim of optimizing both hemodynamics and bioprosthesis durability. The device can be implanted as a subcoronary or modified subcoronary valve replacement, as a complete aortic root replacement (total root), or as a root inclusion. Initial implantations in human subjects began in 1992, and the device has been approved for clinical use in the United States since 1997. The implantation technique of this prosthesis is similar to that for CVG replacement described above. Bach and colleagues[26] reported the 8-year results of a multicenter cohort of 700 patients (of whom 93 percent were over 60 years of age) followed prospectively who received various configurations of this prosthesis. A total root replacement was performed in 162 of those patients, with actuarial freedom from valve-related death of 92.3 percent, freedom from structural deterioration of 100 percent, and freedom from moderate or more aortic regurgitation of 98.7 percent. Oral anticoagulation is not required postoperatively.

## HOMOGRAFT AORTIC ROOT REPLACEMENT

Aortic root replacement can be performed with a cryopreserved homograft aortic root. This operation is more technically demanding because of the less rigid nature of the tissue used. The operative technique is similar to the techniques described above except that many authors advocate a continuous running suture for the implantation of the left ventricular outflow tract side to the annulus. In addition, this proximal suture line must be planar; that is, it should not follow the scallops of the aortic annulus but should run somewhat under the commissures. This operation is particularly well suited for patients in the age range of 40 to 60 years

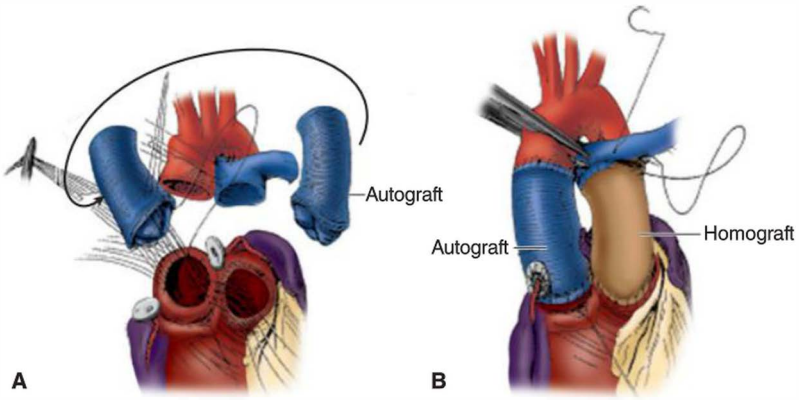

**FIGURE 33-6** Insertion of a pulmonary autograft into the aortic position (Ross procedure). The pulmonary autograft is seated in the aortic annulus with interrupted simple sutures (**A**). Attention is paid to ensure that the valve is properly seated, as the pulmonary valve does not have the differences in valve cusp edge lengths that the aortic valve has. The homograft is sutured into position in the native pulmonary outflow tract to complete the procedure (**B**). (Reproduced with permission from Svensson LG, Crawford ES. Aortic dissection and aortic aneurysm surgery: Clinical observations, experimental investigations, and statistical analyses: Part III. *Curr Probl Surg* 1993;30:1–72. Copyright Elsevier.)

(e.g., those with congenital bicuspid aortic valve pathology) who require aortic root replacement but do not wish to take oral anticoagulants. In addition, homograft root replacement is the operation of choice for extensive native and PVE. The analysis by McGiffin and associates[27] showed that the use of homografts in patients under 40 years of age was associated with an unacceptably high incidence of valve failure over a 15-year period. They demonstrated improved freedom from recurrent endocarditis when allograft tissue was used for aortic valve replacement compared with the use of prosthetic valve material. Grinda and colleagues[28] evaluated the short- and long-term results of cryopreserved aortic viable homograft (CAVH) in the treatment of active aortic endocarditis. One hundred four patients underwent CAVH replacement for active aortic valve endocarditis; 73 percent of those operations involved the native aortic valve, and 27 percent involved a prosthetic aortic valve. CAVHs were inserted using the aortic root replacement technique in 89 percent of those patients. Actuarial survival at 10 years was 83 percent, with 93 percent of the patients free from cardiac death. At 10 years, the actuarial rate for freedom from reoperation was 76 percent and that for freedom from recurrent endocarditis was 93 percent. No thromboembolic complications were observed.

## ROSS PROCEDURE

The Ross procedure consists of removal of the native aortic valve and root with preservation of the coronary buttons, followed by excision of the patient's own pulmonary valve encased in the pulmonary artery distally and a small rim of right ventricular outflow tract muscle proximal to the annulus. It is mandatory to rule out any abnormalities in the pulmonary valve (fenestrations) and significant mismatch in the size of the aortic root and right ventricular outflow tract before proceeding with the autograft explants. Close attention needs to be paid to any anomalous coronary artery crossing the right ventricular outflow tract and preserving the first septal branch of LAD as one proceeds with excision of the autograft. The pulmonary valve, after excision, is translocated to the aortic position as a root replacement, with sewing of the right ventricular muscle to the aortic annulus in a planar fashion, reimplantation of the coronary ostia, and a distal anastomosis between the pulmonary arterial end of the autograft and the ascending aorta. The right ventricle–pulmonary artery side then is reconstructed with a valved pulmonary homograft (Fig. 33-6). This procedure should be performed by surgeons who are extremely competent at aortic root operations. Although the procedure is very demanding technically, the results are outstanding, with 80 percent freedom from reoperation at 20 years,[29] with the failures roughly evenly distributed between the autograft and allograft sides. Recent reports have shown early dilatation of the autograft with neoaortic valve insufficiency (Fig. 33-7).[30] Histologic analysis shows evidence of medial degeneration in both the aorta (Fig. 33-8) and the pulmonary artery of patients with bicuspid compared with tricuspid aortic valves.[31] This is not surprising since embryologically the aorta and the pulmonary artery develop from a common truncus. Over time, gradual dilatation of the neosinuses of Valsalva is observed. This may be addressed by incorporation of aortic root stabilization adjuncts during the time of initial surgery.[32] In light of these data and given its technically demanding nature, many surgeons have tempered their enthusiasm for the Ross procedure and reserve it for young patients especially children who need a biologically viable root to achieve optimal growth.

## VALVE-SPARING AORTIC ROOT REPLACEMENT

Approximately 30 percent of patients who require aortic root replacement have a normal aortic valve that leaks because of

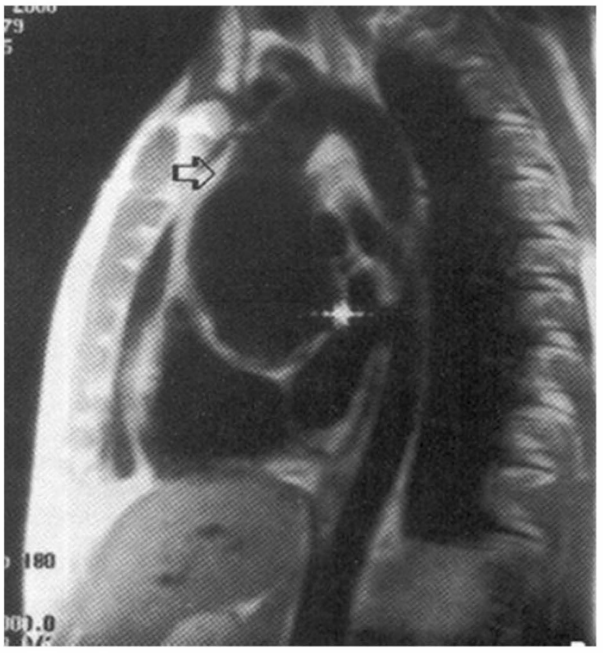

**FIGURE 33-7** Magnetic resonance image of the neoaortic root demonstrating dilatation of the pulmonary autograft and an abrupt transition to normal diameter at the distal suture line, as shown by the arrow. (Reproduced with permission from Sundt TM, Moon MR, Xu H. Reoperation for dilatation of the pulmonary autograft after the Ross Procedure. *J Thorac Cardio Surg* 2001;122(6):1249–1252. Copyright Elsevier.)

sinotubular junction effacement and/or aortic annular dilatation secondary to degenerative causes or connective tissue diseases such as Marfan syndrome. Rather than excising the aortic valve and replacing the root with prosthetic valve material, an operation that encloses the native valve within normal aortic root geometry should restore competency. In 1979, Sir Magdi Yacoub introduced an aortic valve-sparing root replacement ("remodeling," David-II) procedure consisting of excision of all the native aortic tissue except for a small rim around the valve leaflets.[5] An appropriately sized Dacron graft then is fashioned into three scallops at one end and sutured to the residual aortic tissue, followed by coronary reimplantation (Fig. 33-9).

In approximately 1988, Dr. Tirone David introduced the valve-sparing "reimplantation" (David-I) procedure,[6] in which sutures placed *proximal* to the aortic valve annulus are sewn to the Dacron graft. In this way, when the graft is seated, the valve sits entirely inside the graft and is attached to it from the inside with a second suture line after coronary reimplantation. The appropriate graft size is selected by measuring the average aortic valve leaflet height in millimeters, multiplying this value by 4/3, and adding 4 to 6 mm to this number to account for the thickness of the left ventricular outflow tract under the aortic annulus.[12]

The Yacoub remodeling procedure does not protect the aortic annulus and leaves it susceptible to dilatation and hence valvar insufficiency over time. David addressed this problem by placing a Teflon felt buttress under the fibrous portion of the annulus (David-III) but abandoned

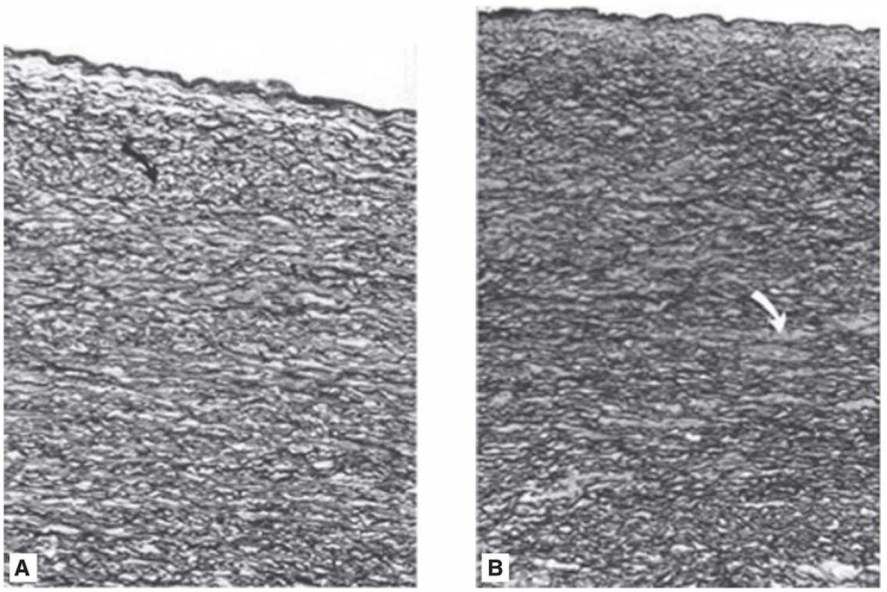

**FIGURE 33-8** **A.** Histologic features of aortic section from a patient with normal trileaflet aortic valve. There are no intimal changes. **B.** Histologic features of the ascending aorta from a 33-year-old patient with bicuspid aortic valve disease. Note the significant medial destruction and the accumulation of mucoid material (arrow). There is a marked fragmentation of elastic tissue. (Reproduced with permission from de Sa M, Moshkovitz Y, Butany T, David TE. Histological abnormalities of the ascending aorta and pulmonary trunk in patients with bicuspid aortic valve disease. *J Thorac Cardiovasc Surg* 1999;118(4):588–594. Copyright Elsevier.)

**FIGURE 33-9** Operative technique of the remodeling (Yacoub) valve-sparing aortic root replacement. (Reproduced with permission from Yacoub MH, Gehle P, Chandrasekaran V. Late results of a valve-preserving operation in patients with a neurysms of the ascending aorta and root. *J Thorac Cardiovasc Surg* 1998:115(5);1080–1089. Copyright Elsevier.)

that modification in favor of the reimplantation procedure. If reoperation is required because of valvar incompetence after the remodeling procedure, a full aortic root replacement is necessary because of the persistence of unprotected native aortic root tissue. In contrast, with the David reimplantation procedure, the entire aortic root and annulus are enclosed in graft material, preventing dilatation over time. If reoperation is required, the graft can be opened, the native valve can be excised, and a stented or stentless valve of choice may be sutured directly into the graft, obviating the need for a much more difficult root re-replacement.

With the original David operation, isolated case reports described native valve failure with fibrotic, retracted aortic leaflets seen at reoperation, perhaps consistent with repeated trauma to the leaflets secondary to the lack of "neosinuses" produced with the Yacoub procedure.[33] The David procedure has undergone two iterations to address this issue. The first (David-IV) involved the selection of a graft 4 to 6 mm larger in diameter than the calculation dictates and plication of the neosinotubular junction down to the correct size. With the current (David-V) modification, the Dacron graft used for the aortic root replacement is oversized by 6 to 8 mm in diameter and then pleated at the annular and new sinotubular junction.[34] The graft will billow outward when it is subjected to arterial pressure, thus creating neosinuses. At Hopkins (Fig. 33-10), we use a modified David I reimplantation procedure using the Valsalva graft, which has prefashioned pseudosinuses.[35] Our procedure differs from the original David I reimplantation technique in that only three subannular sutures are placed. The subannular sutures serve only to anchor the base of the graft below the annulus, holding the entire aortic valve complex within the graft and are not hemostatic. We believe that use of the Valsalva graft in a reimplantation procedure provides both annular stabilization and preservation of sinuses. The size of the graft is based on optimal sinotubular junction sizing using valve sizers, determined intraoperatively after transection of aorta. A graft that is 2 to 3 mm larger is chosen as the graft will sit outside the aortic valve complex. Most patients in our experience[35] have had optimal sinotubular junction diameters of 28 to 30 mm and end up receiving a 30- to 32-mm graft. We have not found that measurement of leaflet dimension and formulas for graft selection are useful. The Valsalva graft is available in sizes 24 to 34 mm, which can accommodate majority of aortic roots encountered in clinical practice. Although patients with annular diameters greater than 34 mm may undergo valve sparing root surgery, in our experience, these patients typically have thin, stretched out abnormal leaflets and often have severe valvular regurgitation. Surgeon experience and patient selection are important factors for good outcomes after VSRR. Modified Bentall operation still remains the procedure of choice in patients with severe regurgitation, leaflet asymmetry, and fenestrations and those having bicuspid valves with significant thickening or prolapsed.

The results of the David operation have been excellent, with 100 percent freedom from reoperation in Dr. David's hands.[36] Similar excellent results have been reported by other investigators.[35] Patients benefit from the long-term durability associated with preservation of their own valves, and anticoagulation is not required postoperatively.[35,36]

## Postoperative Care and Surgical Results

Immediate postoperative care should focus on control of hypertension (for which intravenous sodium nitroprusside is used most commonly) and maintenance of adequate filling pressures (central venous pressure 10–15 mm Hg, pulmonary capillary wedge pressures in the range of 15–18 mm Hg). Dual-chamber pacing is required in a small proportion of patients who leave the operating room in conduction block. Often this resolves within 24 to 48 h. If conduction block persists longer than 4 to 5 days, permanent pacemaker insertion should be considered. In patients with no conduction disturbances, pacemaker wires can be removed on the third or fourth postoperative day. The patient should be placed

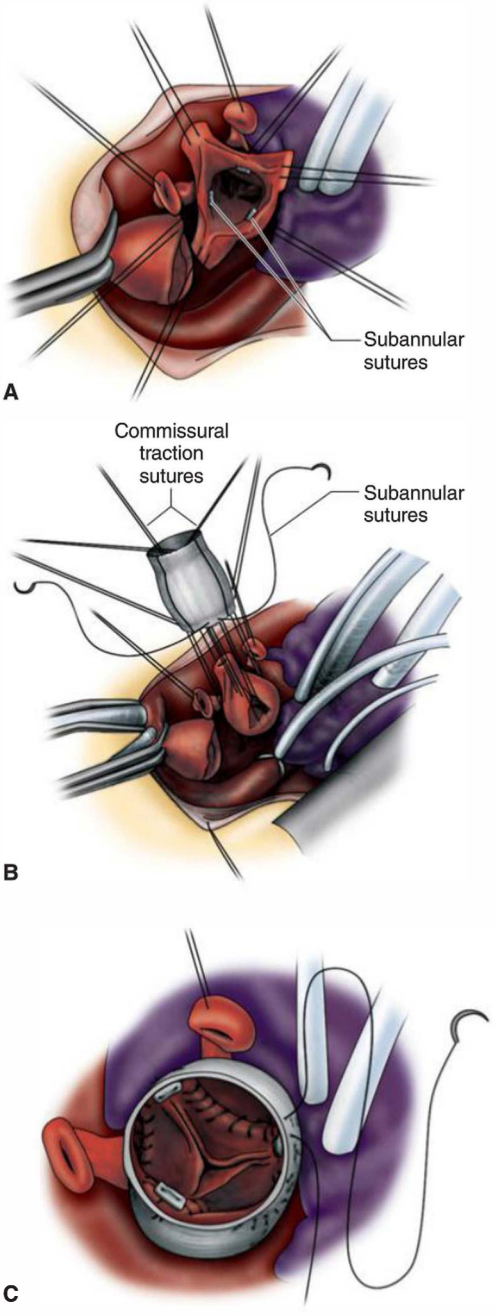

**FIGURE 33-10** Reimplantation (David-I) valve-sparing aortic root replacement- the Hopkins modification. **A.** Stay sutures are placed above each coronary artery, and the sinuses are excised, leaving a 4- to 5-mm sinus remnant attached to the annulus. The coronary arteries are widely mobilized; the dissection remains close to the annulus rather than the coronary to avoid "button-holing" the undersurface of the coronary artery. The area of fibrous continuity between the aorta and pulmonary artery should be separated down to a level flush with the nadir of the right sinus annulus. Some dissection of right ventricular muscle from the aorta at the anterior (right-noncoronary) commissure is sometimes necessary, but one should avoid overzealous use of the cautery here, as our only case of permanent heart block necessitating a permanent pacemaker resulted from a thermal or electrical injury to the AV node during this dissection. In our technique, pledgetted mattress sutures of 2-0 Tevdek are placed about 2 mm below the nadir of the annulus in each of the three sinuses; only two subannular sutures are used if a bicuspid valve is present. The mattress suture should not be too wide, as it may distort the base of the leaflet. If the surgeon prefers, additional subannular sutures can be placed but our experience suggests they are rarely necessary, as the bottom suture line is to secure the graft below the valve and not for hemostasis. Additional subannular sutures can be placed after the graft is lowered and the initial subannular sutures are tied. This will allow the additional subannular sutures to follow the natural curve of the annulus and be accurately placed through the graft, rather than be placed in a single plane, which is difficult to achieve near the left–right commissure, and places the conduction system at risk anteriorly. **B.** The horizontal mattress subannular sutures are passed from inside out through the bottom collar of the graft. The commissural stay sutures are retrieved through the graft, which is then lowered and the three subannular sutures are tied. Using pledgetted 4-0 Prolene sutures, we fix the top of the commissures, just above the valve leaflets, to the STJ of the graft. This height is appropriate for the majority of patients. This usually creates some tension on the commissures, but one should resist the temptation to locate the commissure lower, which will result in leaflet prolapse. The Prolene sutures are tied outside the graft, and the stay sutures are removed. **C.** The internal suture line approximating the annulus and sinus remnant to the inside of the graft is the next step. We begin in the left coronary sinus, using a continuous 4-0 Prolene and an RB-1 needle. Whenever possible, one should direct the needle away from the valve to minimize the chance of leaflet injury. As this is the hemostatic suture line, it should be completed meticulously and in unhurried fashion. Folds of the graft are sites of potential internal leak and bleeding and can be avoid by pulling on the aortic tag at the top of the commissure, straightening the course of the annulus and graft to facilitate sewing. We prefer to perform the internal sutures line in the order of left sinus, noncoronary sinus, and finally, the right sinus. (Reproduced with permission from Cameron DE, Vricella LA. Valve-sparing aortic root replacement with the Valsalva graft. *Op Tech Thorac Cardiovasc Surg* 2009;14:297–308. Copyright Elsevier.)

on telemetry for the duration of the hospital stay, however. The mediastinal tube is removed for outputs less than 150 mL per 24 h.

Patients with mechanical valves are started on oral warfarin on the second postoperative day. The use of daily aspirin coupled with a target International Normalized Ratio (INR) of 2.0 to 2.5 provides satisfactory anticoagulation and minimizes long-term bleeding and thrombotic events. Patients with bioprosthetic valves can be managed with aspirin alone, with no warfarin required.

The 30-day (early) mortality for aortic root replacement varies from 0 to 10 percent.[25,35] This number is approximately doubled with redo operations. Reoperation for mediastinal hemorrhage should be required in less than 10 percent of cases. Complete heart block requiring pacemaker insertion occurs in about 1 to 2 percent in most series. Stroke occurs

in approximately 1 to 4 percent of these patients. There is no practical pharmacologic strategy for the prevention of postoperative atrial fibrillation, which occurs up to one-third of the time (in patients with no previous history). Careful correction of electrolytes and chemical cardioversion with intravenous and oral amiodarone are preferred and are successful 90 to 95 percent of the time. Patients should be maintained on oral amiodarone for approximately 1 month, by which time the threat of recurrent atrial fibrillation should be resolved. In patients who require warfarin, the use of amiodarone makes it very difficult to manage the INR, and consideration should be given to alternative antiarrhythmics such as sotalol and procainamide. Patients with persistent atrial fibrillation despite attempts at chemical and electrical cardioversion should be maintained on oral warfarin until the arrhythmia resolves.

## SUMMARY

Improvements in surgical technique, modifications of the procedure, and the development of specialized graft materials have improved the outcomes of aortic root replacement significantly.

Risk factors for the development or accelerated growth of ascending AAs include aortic dissection, aneurysmal disease elsewhere in the aortic wall, smoking, renal failure, and diastolic hypertension. Ascending aortic dilatation can result from genetic conditions such as Marfan syndrome, congenital bicuspid aortic valve, and osteogenesis imperfecta as well as from excessive extracellular matrix degradation caused by unregulated activity of enzymes such as MMPs, as seen in inflammatory conditions. Aneurysmal enlargement of the aortic root can occur with an increase in the diameter of the aortic annulus (annuloaorticectasia) or without dilatation of the aortic annulus (degenerative disease).

Although certain patients may present with associated symptoms such as onset of pain from acute aortic dissection, the majority of these patients do not present with any specific physical abnormality, and many ascending AAs are detected as an incidental finding. Contrasted CT scans or MRIs, particularly those with three-dimensional reconstructions, have become the most useful diagnostic tests for evaluating the aortic root. There is no medical therapy for ascending aortic root aneurysms, and beyond therapy for blood pressure reduction and careful follow-up, including frequent radiologic imaging, surgical replacement of the aortic root is the only treatment.

For patients in whom surgical replacement of the aortic root is indicated, the surgeon must choose the appropriate ascending aortic root replacement device. Current options for aortic root replacement include composite synthetic xenograft valve-conduit prostheses and homograft replacement. Additional options include using the patient's own pulmonary valve after transposition to the aortic position (Ross procedure) and valve-sparing aortic root replacement.

## AORTIC ROOT REPLACEMENT BOARD REVIEW QUESTIONS (CHAPTER 33)

1. Which of the following is correct regarding the modified Bentall procedure?
   A. Originally proposed by Kouchoukos
   B. Involves separate reimplantation of the coronary buttons
   C. Is the current preferred technique for aortic root replacement
   D. Prevents pseudoaneurysm developed at the coronary ostia
   E. All of the above

2. Which is correct concerning valve-sparing root replacement with the David I technique?
   A. Recreates the sinuses of Valsalva
   B. Precedes the Yacoub technique
   C. Stabilizes the aortic root with sutures placed distal to the aortic annulus
   D. Utilizes a straight tube graft
   E. The incidence of aortic insufficiency is higher than with the remodeling technique

3. Which has been shown to reduce aneurysm growth in Loeys–Dietz syndrome?
   A. Doxycycline
   B. ARB2 inhibitors
   C. β-Blockers
   D. Diuretics
   E. ACE inhibitors

4. Which dimension is correct for consideration of surgery to replace the ascending aorta?
   A. No history of connective tissue disorder—5.5 cm
   B. Marfan syndrome—5.0 cm
   C. Bicuspid aortic valve—4.5 cm
   D. Loeys–Dietz syndrome—4.0 cm
   E. All of the above

5. Which is not a common complication of the Ross procedure?
   A. Bleeding
   B. Injury to the first septal perforator
   C. Heart block
   D. Dilation of the autograft
   E. Thrombosis of the pulmonary homograft

## ANSWERS

1. **Answer: E.** The current preferred technique for aortic root replacement is the modified Bentall procedure, which requires reimplantation of the coronary arteries. This modification was proposed by Kouchoukos as a solution to the problem of coronary ostia pseudoaneurysm that occurred after other operations.
2. **Answer: D.** The David I operation uses a straight tube graft and does not recreate the sinuses of Valsalva. It was introduced after the Yacoub remodeling technique and stabilizes the root with sutures placed proximal to the aortic annulus. The incidence of aortic insufficiency is lower when compared to the remodeling technique.
3. **Answer: B.** Losartan has been shown to slow growth of aneurysms associated with Loeys–Dietz syndrome.
4. **Answer: E.** These are the generally accepted dimensions for surgical intervention for aneurysm of the ascending aorta.
5. **Answer:** E. Stenosis and/or insufficiency occurs in the pulmonary homograft in up to 20 percent of patients, but thrombosis is rare. The combined use of the autologous pulmonary valve and the homograft pulmonary valve is suitable for young, active patients that desire to avoid anticoagulation.

# 34 Mitral Valve Pathophysiology

*Tomasz A. Timek*
*James I. Fann*

**KEY CONCEPTS**

- The normal mitral valve annulus is a saddle-shaped structure with 3:4 ratio of the anterior–posterior to commissure–commissure distance.
- Mitral stenosis is usually a result of rheumatic fever, and valvular pathology represents antigen cross-reactivity from Group A streptococcus resulting in valvulitis, myocarditis, or pancarditis.
- Fibroelastic deficiency and Barlow disease are the predominant forms of degenerative mitral valve disease leading to mitral regurgitation. Fibroelastic deficiency is found in older patients whereas congenitally excessive valve tissue seen in younger patients is observed with Barlow valve.
- Chordal rupture is the most common etiology of mitral regurgitation in degenerative mitral valve disease.
- Ischemic mitral regurgitation (IMR) is associated with a localized left ventricular infarct with subsequent chamber remodeling and perturbation in the subvalvular apparatus. Functional mitral regurgitation (FMR) is associated with end-stage dilated cardiomyopathy.
- Both FMR and IMR are characterized by subvalvular remodeling and annular dilation.
- Leaflet remodeling may contribute to the pathophysiology and severity of both IMR and FMR.
- Annular dilation and perturbed leaflet coaptation tend to be symmetric in FMR and asymmetric in IMR.

## ANATOMY

The mitral valve comprises two leaflets with the anterior leaflet being larger and sail-like traversing approximately one-third of the annular circumference. The posterior leaflet is smaller, more rectangular-shaped, and typically has three scallops denoted as P1, P2, and P3 from the anterolateral toward the posteromedial commissure. Corresponding coapting regions of the anterior leaflet are labeled as A1, A2, and A3 according to the Carpentier nomenclature, although no anatomic landmarks, such as distinct interscallop clefts found in the posterior leaflet, separating these regions exist (Fig. 34-1). The free edge of the leaflets is called the bare or membranous zone, with the remainder of the leaflets termed the rough zone. The histologic structure of the leaflets includes the fibrosa, a solid collagenous core that is continuous with the chordae tendineae, and the spongiosa that consists of few collagen fibers but abundant proteoglycans, elastin, and mixed connective tissue cells, which is on the atrial surface and forms the leaflet leading edge. On the atrial aspect of both leaflets, this surface (the atrialis) is rich in elastin whereas the ventricular side (the ventricularis) is much thicker, is confined mostly to the anterior leaflet, and is densely packed with elastin. Nutrients to leaflet tissue are supplied by annular and ascending chordal vessels. The leaflets have long been thought to be passive, inert structures at the hemodynamic mercy of the ebb and flow of ventricular contraction, but recent data refute this view. Leaflet tissue is richly innervated, has intrinsic contractile properties, complex heterogeneous ultrastructure, and may be important in modulating timely and efficient valve closure.[1,2]

The mitral annulus is a less well-defined structure (particularly the posterior component) without a clear "ring" configuration that anchors the base of the leaflets. It has two major fibrous components, termed the trigones. The right fibrous trigone is part of the central fibrous body of the heart, being in continuity with the aortic valve, the tricuspid valve, and the membranous septum. The portion of the annulus that anchors the anterior mitral leaflet is in direct continuity with portions of the left and noncoronary aortic

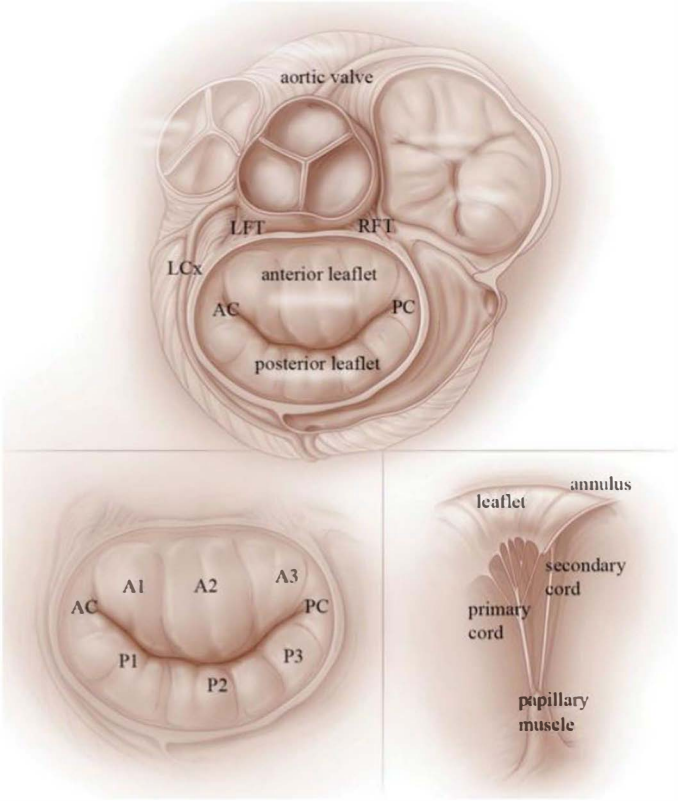

**FIGURE 34-1** Anatomy of the mitral valve complex. LCx, left circumflex coronary artery; RFT, right fibrous trigone; LFT, left fibrous trigone; AC, anterior commissure; PC, posterior commissure.

valve leaflets. The intertrigonal distance defines the fibrous or anterior portion of the mitral annulus and, like the height of the anterior mitral leaflet, is an important clinical marker for surgical annuloplasty sizing as the fibrous annulus has been thought to remain unchanged across the spectrum of mitral disease; however, this region may remodel in ischemic mitral regurgitation (IMR) and functional mitral regurgitation (FMR). The posterior, or lateral, annulus is mostly muscular and manifests most of the dynamic shape and area change of the mitral opening during the cardiac cycle. The normal mitral valve area ranges between 4 and 6 $cm^2$ whereas the normal annular diameter ranges between 5 and 11 $cm^2$ and maintains a 3:4 ratio of the anterior–posterior to the commissure–commissure distance. The annulus has a saddle-shaped configuration with the highest points located anteriorly and posteriorly and the lowest points located at the commissures. This three-dimensional annular structure may be important for proper leaflet stress distribution and effective valve closure. The annulus increases in size during early diastole and decreases rapidly during late diastole and early systole with most of size reduction achieved before ventricular contraction.[3] It becomes less planar during systole as the anterior portion of the "saddle" becomes more accentuated simultaneously optimizing mitral valve closure and left ventricular (LV) outflow tract size during the period of ejection. In addition, the mitral annulus descends toward the LV apex during systole; the duration, average rate, and magnitude of annular displacement correlate with the rate of left atrial filling and emptying.

There are two major papillary muscles that support the mitral valve. Both papillary muscles provide chordae tendinae to both mitral leaflets. The anterolateral papillary muscle usually has one major head and is larger; the posteromedial papillary muscle is flatter and can have two or more heads. Vascular supply to the anterolateral papillary muscle is usually from both the left anterior descending and the circumflex arteries, while the posteromedial papillary muscle is often supplied only by the posterior descending artery. First-order chordae, designed to prevent leaflet prolapse, arise near the tips of the papillary muscles and insert into the leading edge of the leaflets while second-order chordae insert farther back into the leaflet, either on the rough zone or at the junction between the rough zone and the clear zone. These chordae are larger and thicker and serve to stabilize the valve, maintain valvular–ventricular continuity, and aid ventricular systolic performance. Third-order chordae arise from ventricular wall trabeculations and insert near the annulus. The chordae also serve as scaffolding for nutrient vessels to supply leaflet tissue while their ultrastructural composition is related to their function.[4]

## MITRAL STENOSIS

Mitral valve stenosis is usually the result of rheumatic fever suffered in childhood or early adulthood. A definite history of rheumatic fever can be obtained in only about 50 to 60 percent of patients; women are affected more often than men by a 2:1 to 3:1 ratio.[5] Nearly always acquired before age 20, rheumatic valvular disease becomes clinically evident one to three decades later. Rheumatic disease remains a significant problem throughout the world, although its incidence has fallen sharply in industrialized countries. Rheumatic heart disease is a result of antigen cross-reactivity from group A β-hemolytic *Streptococcus* culminating in pancarditis, affecting valve leaflets, endocardium, and myocardium to varying degrees. Mimicry between streptococcal antigens and cardiac tissue proteins, combined with high inflammatory cytokine and low interleukin-4 production, leads to the development of autoimmune reactions and cardiac tissue damage.[6] Mitral valve involvement is the most common, followed by combined mitral and aortic involvement. Commissural fusion, chordal fusion and shortening, and leaflet fibrosis and retraction as well as significant calcifications are most commonly seen in rheumatic mitral valve disease. Grossly, the mitral opening takes on the classically described "fish mouth" appearance (Fig. 34-2).

Physiologically, mitral stenosis elevates the transvalvular gradient during diastole between the left atrium and the left ventricle, leading to restricted ventricular filling and increased left atrial pressure. Mean valve area of less than 1.0 $cm^2$ and a mean transvalvular gradient greater than 10 mm Hg is considered to be severe mitral stenosis. The transvalvular pressure gradient is a function of the square of the transvalvular flow rate; thus, high transvalvular gradient may be associated with a normal cardiac output, but if cardiac output is low, only a modest transvalvular gradient may be present. In addition, mitral transvalvular flow depends on cardiac output and heart rate. An increase in heart rate decreases the duration of LV filling during diastole and consequently increases the mean transvalvular gradient and left atrial pressure. The dynamic nature of the transvalvular gradient may therefore become significant and hence cause symptoms only with exercise; however, chronic and progressive valvular stenoses are usually accompanied by elevated left atrial pressures and increased pulmonary vascular resistance and pulmonary hypertension. Maintenance of sinus rhythm becomes paramount as atrial contraction augments flow through the stenotic valve, thereby helping to sustain adequate forward cardiac output. However, the dilated atrium becomes substrate for development of atrial fibrillation, which significantly limits ventricular filling. The development of atrial fibrillation decreases cardiac output by 20 percent or more; atrial fibrillation with a rapid ventricular response can lead to acute dyspnea and pulmonary edema. Major determinants of atrial fibrillation in patients with rheumatic heart disease include older age and larger LA diameter.[7] The risk of intra-atrial thrombus from stagnant flow within the enlarged chamber increases concurrently.

**FIGURE 34-2** Autopsy specimen of mitral stenosis. Heavy calcification of the both mitral leaflets with classic "fish mouth" shape of the stenotic mitral orifice.

Isolated mitral stenosis is associated with LV chamber size that is normal or smaller than normal with typically low end-diastolic pressure. Cardiac output is diminished due to underfilling of the ventricle from inflow obstruction rather than LV myocardial dysfunction. During exercise, LV ejection fraction may increase, but this response is blunted by the shorter diastolic filling periods at higher heart rates; therefore, stroke volume and cardiac output do not increase proportionally to physiologic demand. In approximately 25 to 50 percent of patients with severe mitral stenosis, LV systolic dysfunction is present as a consequence of associated problems (e.g., mitral regurgitation, aortic valve disease, ischemic heart disease, rheumatic myocarditis or pancarditis, and myocardial fibrosis), and in these patients, LV end-systolic and end-diastolic volumes may be larger than normal. In severe chronic mitral stenosis with elevated pulmonary vascular resistance, pulmonary arterial pressure is elevated at rest and can approach systemic pressure with exercise. A pulmonary arterial systolic pressure greater than 60 mm Hg significantly increases impedance to right ventricular emptying and produces high right ventricular end-diastolic and right atrial pressures as well as eventual tricuspid insufficiency.[8] In time, right ventricular systolic performance deteriorates.

## MITRAL REGURGITATION

Structural changes of the mitral valve may produce valvular insufficiency by adversely impacting one or more components of the mitral valve complex: mitral annulus, mitral leaflets, chordae tendinae, or LV geometry. Carpentier classified mitral regurgitation into three main pathoanatomic types based on the leaflet motion: normal leaflet motion (type I), leaflet prolapse or excessive motion (type II), and restricted leaflet motion (type III).[9] Type III is further subdivided into types IIIa and IIIb based on leaflet restriction during

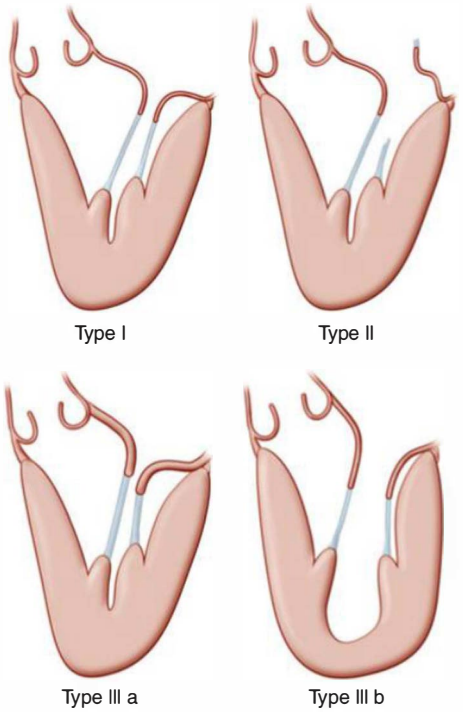

FIGURE 34-3 Schematic representation of Carpentier classification of mitral leaflet motion.

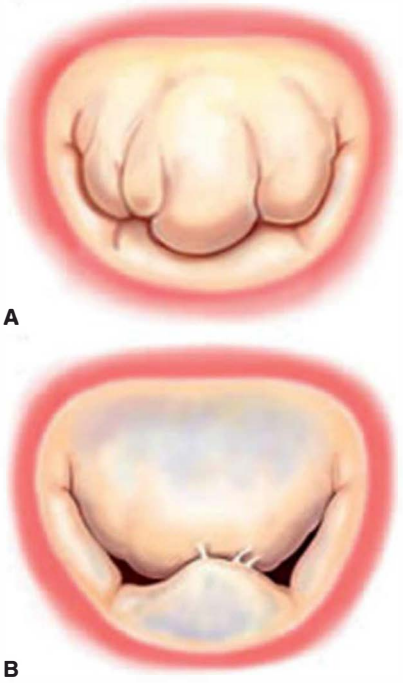

FIGURE 34-4 Degenerative mitral valve disease. **A**. Barlow disease with anterior leaflet prolapse. **B**. Fibroelastic deficiency with ruptured chordae to P2 segment of the posterior leaflet.

diastole (type IIIa) or during systole (type IIIb) (Fig. 34-3). Mitral regurgitation with normal leaflet motion can be the result of annular dilatation usually due to LV remodeling. Leaflet prolapse typically results from a floppy mitral valve with chordal elongation and/or rupture, but rarely can also be seen in patients with coronary artery disease who have papillary muscle elongation or rupture. Mitral regurgitation due to restricted leaflet motion is associated with rheumatic valve disease (types IIIa and IIIb), ischemic heart disease (IMR with type IIIb restricted systolic leaflet motion secondary to apical tethering or tenting), and dilated cardiomyopathy (type IIIb). This elegant classification system allows for standardized nomenclature while reflecting the underlying pathophysiology of mitral insufficiency across a wide spectrum of structural deformities of the mitral valve complex.

## Degenerative Mitral Regurgitation

Degenerative mitral valve disease is a major cause of mitral insufficiency requiring surgical evaluation in the United States. Included in this category are myxomatous degeneration, floppy mitral valve, and mitral valve prolapse. The etiology of mitral valve prolapse is both acquired (*fibroelastic deficiency* in older patients) and congenital or heritable, with excess spongy, weak fibroelastic connective tissue constituting the leaflets and chordae tendineae (*Barlow valve*, in younger patients) (Fig. 34-4). Mitral valve prolapse is most common in young women and can have a familial component; the more severe forms of insufficiency are more common in men.

In myxomatous disease, the mitral leaflets become thickened and opaque and the degenerative process may extend down the chordae and out onto the annulus. Histologically, elastic fiber and collagen fragmentation and disorganization are present, and acid mucopolysaccharide material accumulates in the leaflets.[10] Myxomatous degeneration commonly involves the annulus, resulting in annular thickening and dilatation. All these changes are pronounced in young patients with Barlow valves but can be minimal in older subjects with fibroelastic deficiency, in whom the noninvolved posterior leaflet scallops and anterior leaflet are normal and thin. A minority of patients (5–10 percent) with mitral valve prolapse progress to symptomatic mitral insufficiency; these patients can be placed into three categories: isolated chordal rupture, isolated annular dilatation, and combined chordal rupture and annular dilatation (most common). Chordal rupture can result in acute mitral insufficiency and should be suspected in patients with no previous clinical history of coronary artery disease or acute myocardial infarction. Chordal rupture is typically found in older patients with prolapse due to fibroelastic degeneration without much accompanying leaflet pathology. Posterior chordal rupture, usually subtending just the middle scallop, is

the most frequent finding, followed by anterior chordal rupture and then combined anterior and posterior chordal rupture.

## Functional and Ischemic Mitral Regurgitation

FMR is the result of incomplete mitral leaflet coaptation in the setting of LV dysfunction and dilatation with or without annular dilatation (e.g., dilated cardiomyopathy or ischemic cardiomyopathy). IMR, a subset of FMR, is usually associated with a localized LV insult due to myocardial infarction with subsequent remodeling and geometric perturbations in the subvalvular apparatus. Historically, FMR and IMR occur in the setting of what has been thought as structurally normal mitral valve leaflets and are thus considered "functional." These clinical entities frequently complicate myocardial infarction and carry a poor prognosis in the setting of both coronary disease and idiopathic dilated cardiomyopathy.

"Functional mitral regurgitation" has been used interchangeably to refer to mitral insufficiency due to end-stage ischemic dilated cardiomyopathy and that due to idiopathic dilated cardiomyopathy, yet the mechanisms of mitral regurgitation in these clinical conditions differ significantly.[11] The lack of standardized application of "functional" and "ischemic" etiologies of mitral insufficiency represents a considerable hindrance in the appropriate interpretation and comparison of clinical studies, especially since coronary artery disease and LV dysfunction can span a wide range of clinical presentations. Despite these limitations, many investigators today use "functional" to refer to mitral regurgitation in the setting of severe LV dysfunction and dilation usually defined by an ejection fraction of less that 30 percent regardless of etiology.[12] IMR, in contrast, refers to patients with coronary artery disease and mitral regurgitation with lesser degree of LV dilation, more preserved ventricular function, and more asymmetric ventricular remodeling usually affecting the posterolateral ventricular wall.[13] Not surprisingly, these entities lie on a clinical continuum and cannot always be precisely defined due to the heterogeneity of ischemic heart disease. Animal models of both local and global LV systolic dysfunction and remodeling associated with mitral regurgitation have been developed and permit identification of the contributing geometric factors that result in FMR and IMR in controlled settings.[14,15]

IMR encompasses a difficult patient population that is characterized by high operative mortality, poor long-term outcomes, and frequent recurrent regurgitation after standard surgical repair.[16] Optimal surgical repair and improved clinical outcomes can only be achieved with better knowledge of the pathophysiology of IMR, which is currently incompletely understood. Clinical studies estimate the incidence of postinfarction mitral regurgitation detected on echocardiography to be approximately 20 percent with up to 12 percent of patients having moderate or severe regurgitation.[17,18] In patients who progress to clinically symptomatic heart failure, the incidence of mitral regurgitation reaches 56 percent with approximately 16 percent having moderate or severe regurgitation.[19] By these estimates, approximately 860,000 patients have clinically significant IMR (moderate-to-severe grade) in the United States with the prevalence bound to increase with the aging population and new therapies to improve postinfarct survival. Echocardiographic studies have shown that mitral regurgitation is an independent predictor of heart failure and death in infarct survivors beyond 30 days. The degree of mitral regurgitation shows a graded relation to 1-year postinfarct mortality, and even mild degree of IMR has been shown to have prognostic significance. Similarly, the presence of mitral regurgitation in dilated cardiomyopathy (or FMR) portends a poor prognosis and is associated with high cardiovascular morbidity and mortality in both ischemic and idiopathic etiologies.

The causative mechanism of IMR appears to lie in the annular and ventricular levels rather than leaflet or chordal structure leading to such labels as "ischemic," "functional," and "nonorganic" being clinically applied. Although IMR is a prevailing clinical entity, it has not been consistently defined in the literature adding to considerable confusion and conflicting results. Rankin and colleagues defined IMR as "valvular insufficiency arising from coronary disease without primary leaflet or chordal pathology."[20] Yet this definition appears overly broad as the spectrum of coronary disease and LV dysfunction varies tremendously in IMR ranging from preserved ventricular function to moderate dysfunction to end-stage dilated ischemic and idiopathic cardiomyopathy. A useful definition of IMR was suggested by Replogle who subclassified patients in this group into three entities: (1) sudden-onset mitral regurgitation due to acute myocardial infarction and papillary muscle rupture and/or LV wall dysfunction, (2) mitral regurgitation associated with coronary artery disease with normal mitral leaflets, and (3) mitral regurgitation caused by end-stage ischemic dilated cardiomyopathy.[21] The first of these three etiologies usually represents a catastrophic event with very high mortality but fortunately low incidence. Thus, it is the latter two types of IMR that represent the bulk of the clinical disease.

### LEFT VENTRICULAR GEOMETRY

Mitral regurgitation, whether functional or ischemic in origin, is usually associated with LV dilation; however, the degree of chamber remodeling may differ significantly. In a canine model of dilated cardiomyopathy induced with coronary microembolization, Kono and colleagues found increased LV sphericity, or ventricular globularization, to be closely associated with FMR.[22] Echocardiographic studies in patients with nonischemic dilated cardiomyopathy confirm LV diameter and sphericity to be major predictors of mitral regurgitation; sphericity has also been shown to accompany progression of mitral regurgitation in end-stage ischemic heart disease and recurrent regurgitation after ventricular reduction surgery.[23] IMR, on the other hand, appears not to be solely dependent on global LV dilation but rather on a localized LV insult.[24] Nonetheless, recurrent regurgitation after ring annuloplasty for IMR is associated

with a persistently spherical ventricle underscoring the spectrum of clinical disease and blurring of boundaries between IMR and FMR as LV dysfunction and dilation progress. Experimentally in an ovine model, a small posterior infarct increases cavity size by 48 percent, yet results in no mitral regurgitation after 8 weeks, whereas large infarcts with lesser degree of LV dilation result in immediate severe regurgitation.[25] In a chronic model of ovine posterolateral ischemia, the end-systolic volumes did not differ between animals that did or did not develop significant mitral regurgitation.[24]

Clinically, IMR is thought to be more frequent with inferior than anterior myocardial infarct; however, equal incidence or greater association with anterior infarct has also been reported.[26–28] In an animal model, both large and moderate infarcts of the anterior wall have not been associated with mitral regurgitation even with LV enlargement of 150 percent.[25] These experimental models, however, represent isolated regional ischemia with unaffected remote territory; this scenario does not reflect most clinical settings as the majority of patients with IMR suffer from multivessel coronary artery disease. It is this heterogeneity of human disease that does not permit identification of clear boundaries in the pathogenesis of infarct-specific mitral regurgitation. In the clinical setting, IMR associated with anterior wall infarct is usually accompanied by greater LV and mitral annular dilation, more impressive annular flattening, and substantially reduced ejection fraction compared with findings with inferior infarct.[29,30] Anterior infarct may not sufficiently affect critical annular–subvalvular spatial relationships that are perturbed by a smaller posterolateral infarct, yet with chronic remodeling and deterioration in LV function, IMR does result. Thus, IMR associated with anterior infarct may lie closer on the clinical spectrum to FMR characterized by severely depressed LV function, global LV dilation, and annular enlargement. In contrast, inferior infarct is associated with less global LV dilation and dysfunction but more substantial perturbation of the mitral valve apparatus. Experimentally, surgical interventions used to correct chronic IMR have not been shown to be associated with altered LV size. However, reverse remodeling after restrictive annuloplasty is more predictable in patients with smaller LV size (end-diastolic volume less than 65 mm), and patient survival is superior.

## MITRAL ANNULUS

The mitral annulus is a nonplanar structure in shape of a saddle with significant elevation of the midseptal annulus (also known as the annular "saddle horn"). The three-dimensional shape of the annulus, conserved across mammalian species, may be important for proper leaflet stress distribution. The annulus subsequently flattens with onset of FMR and IMR in both clinical and experimental studies. Progressive and heterogeneous flattening of the annulus was well documented in a chronic study of ovine IMR (Fig. 34-5).[31] Although annular flattening may not be directly related to the pathogenesis of IMR, altered annular shape may act to increase leaflet forces and lead to pathologic remodeling that, in the chronic state, could contribute to the evolution of mitral regurgitation. Naturally, abnormal annular geometry has surgical implication in terms of design and implantation of annular prostheses.

In patients with nonischemic cardiomyopathy and depressed ejection fraction of 25 percent, annular size was the chief determinant of mitral regurgitation.[32] Mitral regurgitation associated with annular dilation may be present in patients with depressed LV function and ventricular remodeling; the degree of annular dilation, especially in the septal–lateral dimension, correlates with the degree of LV systolic dysfunction in patients with dilated cardiomyopathy. Annular dilation and reduced transmitral pressure were found to be responsible for mitral regurgitation in a group of patients with a mean EF of 23 percent, while annular enlargement and ejection fraction were observed to be the strongest predictors of leaflet tenting area in a similar patient population.[33] Experimentally in the canine model of tachycardia-induced cardiomyopathy, mitral regurgitation was predicted

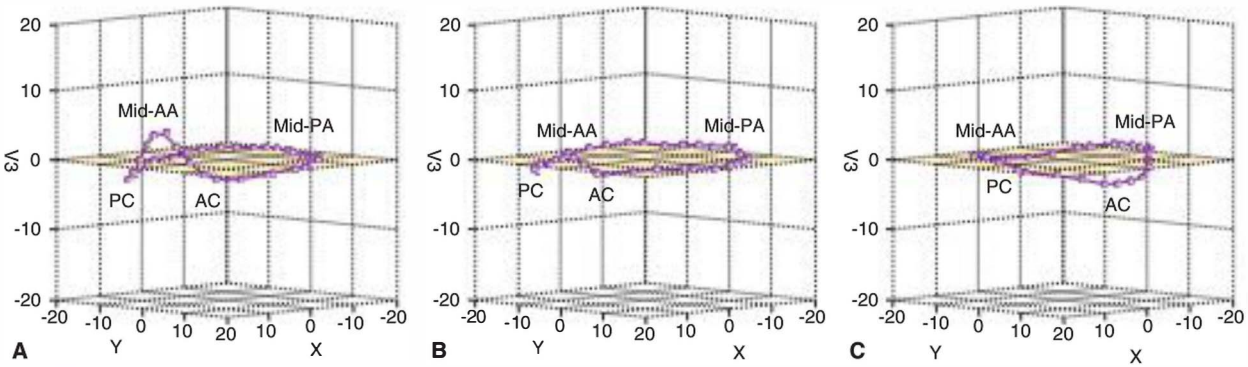

**FIGURE 34-5** The three-dimensional geometry of a single ovine mitral annulus shown **A** at baseline, **B** 1 h after myocardial infarction, and **C** 8 weeks after myocardial infarction. Progressive flattening of the mitral annular three-dimensional structure is observed across time. The positions of the midanterior annulus (Mid-AA), the midposterior annulus (Mid-PA), the anterior commissure (AC), and the posterior commissure (PC) are indicated. (Reproduced from Ryan JB, et al. *Ann Thorac Surg* 2007;84(2):553–559.)

purely by the degree of annular dilation; device-driven increase in annular circumference by 25 percent was found to produce severe mitral regurgitation in healthy dogs.[34] In an *in vitro* porcine valve model, isolated annular enlargement from 6.8 to 12 $cm^2$ increased regurgitant volume from less than 3 to 18.5 mL; in another study, an annular area increase of 1.75 times baseline led to significant increase in mitral regurgitation.[35] In addition, finite element analysis showed that an isolated increase in annular circumference is associated with incomplete leaflet coaptation throughout systole without displacement of the coaptation point. These findings support the notion that mitral regurgitation in end-stage dilated cardiomyopathy is chiefly related to substantial annular dilatation, particularly in the septal–lateral dimension.

In an acute model of IMR provoked by a localized LV insult, annular dilation was a component of the geometric perturbation leading to mitral regurgitation but not the sole etiology.[36] Similar findings have been found by other investigators in both acute and chronic experimental IMR, although acute posterior leaflet interscallop insufficiency may be related to annular dilation alone. These findings are corroborated by clinical studies that identify annular dilation as a contributor to the development of mitral regurgitation; however, subvalvular deformations play the central role. Furthermore, in clinical echocardiographic studies, the pattern of annular dilation in IMR is more asymmetric whereas annular dilation associated with FMR was diffuse and symmetric. With both FMR and IMR, annular perimeters increase (including the septal portion) with bulk of annular dilation along the lateral annulus.[37] Previous studies have shown that the lateral annulus is more susceptible to dilation during acute ischemia, and patients with IMR exhibit decreased motion of the lateral annulus during the cardiac cycle. The lateral annulus undergoes not only substantial dilation but also a decrease in its "sphincteric" action, which reduces mitral annular area during the cardiac cycle. This reduction may be due to decreased LV systolic function as annular contraction is augmented with increased inotropy. Clinically, decreased annular contraction occurs in patients with ischemic and dilated cardiomyopathy and is a predictor of mitral regurgitation.[38] During cardiac resynchronization therapy, resynchronizing annular segments leading to more effective annular contraction is associated with reduced mitral regurgitation in patients with congestive heart failure and left bundle branch block. It is reasonable to conjecture that dysfunctional annular sphincteric mechanism contributes to both FMR and IMR.

## PAPILLARY MUSCLES

Papillary muscle displacement has been identified as a key component in the pathogenesis of IMR; however, isolated papillary muscle dysfunction does not lead to significant mitral regurgitation, and dysfunction of the underlying LV wall is needed to induce clinically important regurgitation.[39] Specifically, systolic dysfunction of the posterior/inferior LV wall inclusive of the posterior papillary muscle with subsequent leaflet tethering appears to be the prerequisite lesion for the evolution of experimental and clinical IMR. Infarction of the anterior wall and the anterior papillary muscle does not result in mitral regurgitation until advanced LV dilation and systolic dysfunction develop. In patients with very low ejection fractions and remarkable LV dilation, synchronization of LV contraction at papillary muscle insertion sites can, however, reduce the degree of mitral regurgitation. Posterior papillary muscle dysfunction has been shown to reduce the severity of mitral regurgitation through effective ischemic "elongation" of the papillary muscles that ameliorates apical leaflet displacement in acute ovine IMR[40] and in patients as the adjacent LV wall remodels. Experimentally, plication of a posterolateral infarct can reduce the degree of IMR through papillary muscle repositioning, thereby underscoring the importance of local subvalvular geometric perturbations associated with IMR. Gorman and colleagues reported apical displacement of the anterior papillary muscle tip and basilar dislocation of the posterior papillary muscle tip in acute ovine IMR; based on papillary muscle position, they postulated that IMR in this model could be associated with leaflet prolapse near the posterior commissure and restriction near the anterior commissure.[41] Accordingly, Nielsen and colleagues observed decreased tension in the chordae emanating from the ischemic posterior papillary muscle but increased tension in those arising from the normally contracting anterior papillary muscle in a porcine model of acute IMR.[42] Such leaflet configuration due to asymmetric papillary muscle dislocation has also been suggested by *in vitro* modeling.

In experimental FMR, anterior and posterior papillary muscle displacement, assessed by the distance from each papillary muscle tip to the midseptal annulus, was almost identical consistent with the symmetric global LV dilation associated with cardiomyopathy. This finding is in contrast to a localized ischemic insult seen in the IMR, where posterior papillary muscle tethering was almost twice as great as that of the anterior papillary muscle. No apical displacement of either papillary muscle tip was observed, but there was impressive increase in the interpapillary distance that has been identified as a marker of LV dilation and predictor of FMR. Also, greater global LV dysfunction and remodeling have been associated with symmetric papillary muscle tethering.

## MITRAL LEAFLETS

Experimental and clinical research has focused primarily on altered annular and subvalvular geometry as the cause of FMR and IMR, while valvular leaflet tissue properties have been thought to be essentially unchanged. However, human studies reveal that both anterior and posterior mitral leaflets remodel in cardiomyopathy, suggesting that leaflet tissue is a contributor to the pathophysiology of FMR. Anatomic and biochemical studies of the mitral valve leaflets have shown normal valvular tissue to be richly innervated and having a complex blood supply, heterogeneous biochemical composition, and nonhomogeneous deformation.[43,44] Recent observations have demonstrated that mitral leaflets from human transplant recipient hearts with FMR have a much different

biochemical profile than control leaflets, having significantly higher DNA content and collagen concentration with greatest deposition in the anterior leaflet free edge.[45] Overall, human heart failure leaflets were 28 to 41 percent longer than control values. Further mechanical analysis revealed that the leaflet tissue was 61 percent stiffer in the radial direction and 50 percent stiffer in the circumferential direction than control leaflets reflecting microstructural alterations. These data suggest prominent biochemical and ultrastructural remodeling of leaflet tissue particularly in the region of the free edge. The anterior leaflet edge and the entire posterior leaflet have been found to have a relatively thin collagenous layer, and these regions may be particularly prone to greater remodeling as annular dilation increases leaflet stresses, and collagen synthesis is upregulated in response. Greater remodeling in the coaptation region of the leaflets may not be surprising given the nonhomogeneous deformation of the anterior leaflet in an *ex vivo* porcine leaflet model.[46] The anterior leaflet in normal porcine valves stretches significantly after valve closure along a radial gradient from the mitral annulus to the leaflet edge. In the ovine FMR model, the greatest anterior leaflet remodeling occurs in the area of maximum deformation, that is, the leaflet-leading edge or free margin.[47] Mitral leaflets, therefore, are not inert flaps strictly bound to the hemodynamic conditions of the left ventricle but rather active components of the valvular–ventricular complex capable of regulating valvular function in health and disease.

Recently, Tibayan and colleagues found significantly increased radii of curvature of both leaflets at 7 weeks after posterolateral infarct in an ovine model.[48] This finding, due to stretching of the leaflets from papillary muscle displacement leading to flattening of leaflet geometry, is consistent with the fact that altered leaflet geometry with concave shape of the leaflets relative to the left atrium is a strong predictor of IMR in the clinical setting.[49] Septal–lateral annular dilation and altered papillary muscle position emerged as predictors of anterior leaflet shape in an animal model[48]; clinically, leaflet length correlated with annular diameter in human transplant recipient hearts.[45] Annular dilation along with subvalvular changes can be expected to stretch leaflet tissue across the valve orifice and alter loading conditions, thus leading to leaflet remodeling as a compensatory mechanism that becomes exhausted as ventricular and annular pathologic changes progress. Such leaflet stretching coupled with annular flattening can be expected in increased stresses on the leaflet and thus induce tissue remodeling as seen in the chronic model of IMR. The possible effects of altered valvular mechanical forces, tissue properties, and biochemical composition associated with FMR and IMR on leaflet remodeling are summarized in Figure 34-6. Recent

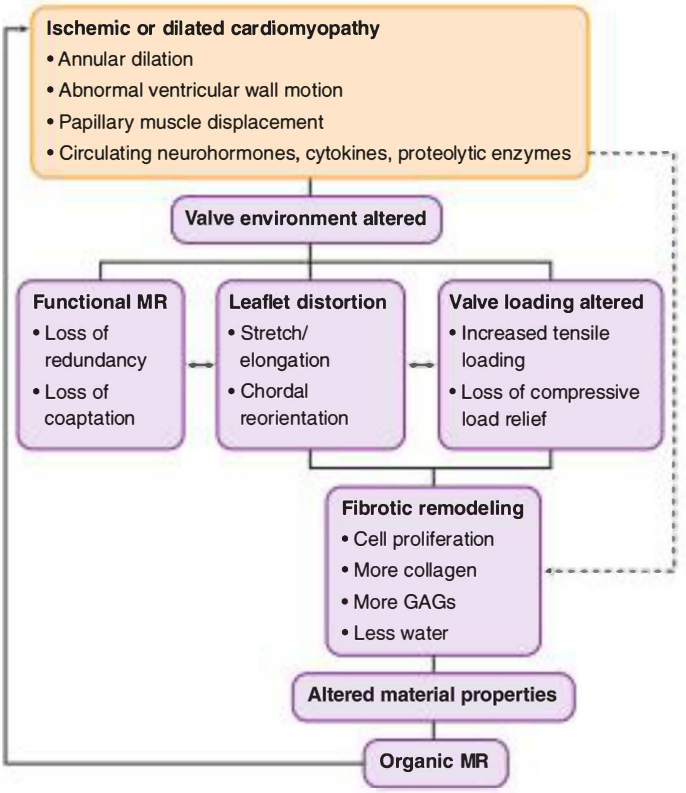

**FIGURE 34-6** Proposed mechanisms for valvular remodeling in IMR and FMR from altered mechanical loads, tissue properties, and biochemical composition of the mitral leaflets. (Reproduced from Grande-Allen KJ, et al. *J Am Coll Cardiol* 2005;45:54–61.)

echocardiographic findings in patients with reduced LV function and previous infarct demonstrated leaflet area enlargement in patients with and without mitral regurgitation, but significant regurgitation was associated only with inadequate leaflet remodeling relative to the demands of subvalvular tethering geometry.[50] Therefore, heterogeneity of leaflet remodeling may partially contribute to the wide spectrum of mitral regurgitation seen clinically. Furthermore, it is conceivable that in the evolution of mitral regurgitation, leaflet motion changes from restriction to normal leaflet motion with progressive chamber dilation and leaflet tissue remodeling, and IMR and FMR represent two points on a clinical continuum.

## LEAFLET COAPTATION

In FMR and IMR, disruption of normal leaflet coaptation is the final common pathway of annular and subvalvular geometric perturbations. It is this coupling that translates the "ventricular" disease of FMR and IMR into a valvular problem of mitral regurgitation. Apical leaflet displacement associated with LV dysfunction was first described as incomplete mitral valve closure and has subsequently been referred to as "leaflet tenting."[51] Since these pioneering efforts, multiple experimental and clinical studies have focused on coaptation depth, also referred to as coaptation height, and leaflet tenting area as representing the sum of geometric deformations leading to mitral regurgitation. These parameters are easily measured with echocardiography or magnetic resonance imaging and lend themselves to quantification (Fig. 34-7). However, IMR can be associated with normal, tethered, or prolapsed leaflet motion with symmetric or asymmetric leaflet deformity. Therefore, increases in tenting area may be due to leaflet tethering, annular dilation, or both.

In experimental FMR, leaflet motion was found to be normal without evidence of restriction or tethering. Therefore, leaflet edges were simply displaced along the main direction of annular enlargement, the septal–lateral diameter, and leaflet occlusion area was exhausted with progressive annular dilation resulting in increased leaflet edge separation.[47] Similar findings were noted echocardiographically in human subjects with dilated cardiomyopathy.[52] Tenting area was larger in patients with FMR secondary to significant annular dilatation, yet coaptation depth also increased; this finding was also thought to be secondary to annular dilation as papillary muscle tethering and chordal length did not change. Although annular dilation may affect coaptation depth if subvalvular geometry remains constant, it is septal–lateral annular enlargement that exhausts mitral leaflet redundancy resulting in mitral regurgitation by decreasing leaflet coaptation length (i.e., the length of leaflet apposition at the coaptation line).

Tethering of both leaflets has also been observed echocardiographically in patients with IMR. Symmetrical leaflet deformation occurred in patients with idiopathic dilated cardiomyopathy, whereas asymmetric leaflet geometry was observed in those with an ischemic etiology, yet all patients showed increased coaptation depth indicative of tethering.[53] Similarly, in patients with mitral regurgitation and prior anterior myocardial infarct, the leaflets were widely tethered

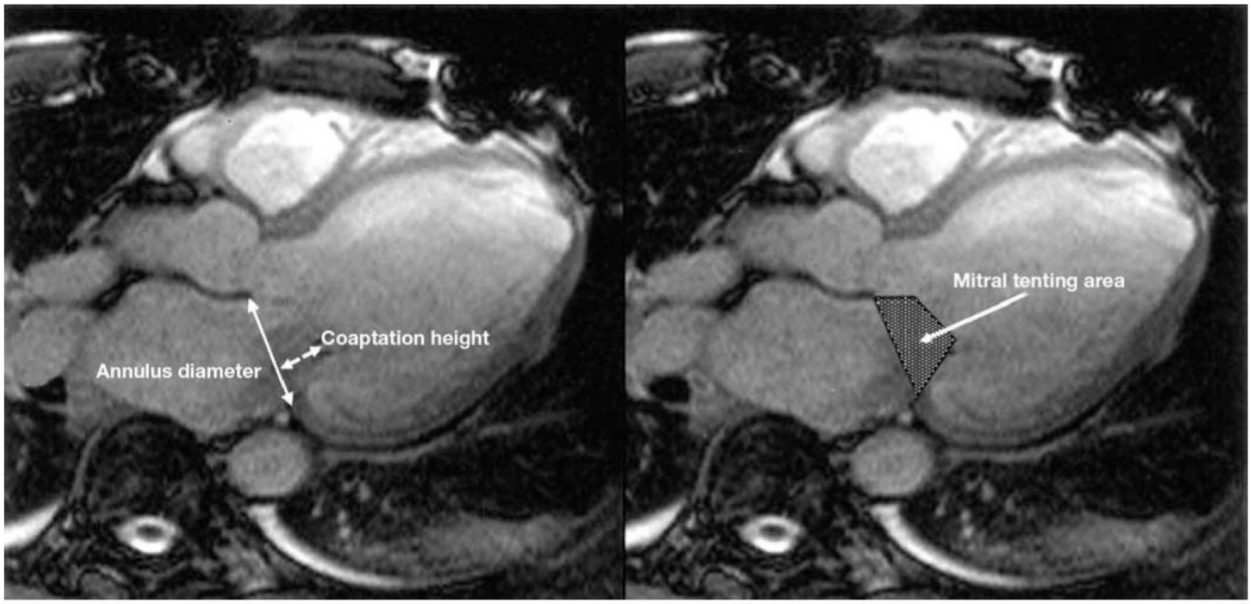

**FIGURE 34-7** Cine magnetic resonance imaging three-chamber view of a patient's heart demonstrating the measurement of annulus diameter and coaptation height (left), and mitral tenting area (right) of the mitral valve. Similar measurements can be derived echocardiographically. (Reproduced from Srichai MB, et al. *Ann Thorac Surg* 2005;80:170–178.)

toward the ventricle, whereas in the setting of inferior infarct, the tethering was more localized and tenting volume reduced. Indeed, leaflet deformation in patients with anterior infarct, characterized by more significant LV dysfunction and dilation, resembles more of the findings observed in idiopathic dilated cardiomyopathy than in localized inferior infarct with preserved LV function. Patients with IMR have significantly increased coaptation depth indicative of tethering compared with those with idiopathic dilated cardiomyopathy and global LV dilation, an entity that is often associated with substantial annular dilation. Valvular tenting and decreased annular contraction are two clinical predictors of effective regurgitant orifice, thereby underscoring the importance of annular enlargement and leaflet tethering in the genesis of mitral regurgitation. This additive effect impacting leaflet coaptation has been demonstrated in a chronic model of IMR[24] (Fig. 34-8). In addition, IMR may not only be a result of dysfunctional leaflet coaptation, but also due to posterior leaflet interscallop separation that is strongly associated with annular dilation. Clearly, IMR embodies a heterogeneous set of leaflet perturbations, and clinical studies corroborate the supposition that IMR and FMR may be associated with different leaflet deformations, although considerable overlap may occur on the clinical spectrum of disease. It is therefore not surprising that leaflet tenting, which represents the sum effect of annular and subvalvular geometric deformations on leaflet coaptation, is consistently identified in FMR and IMR as the main predictor of the severity of regurgitation.

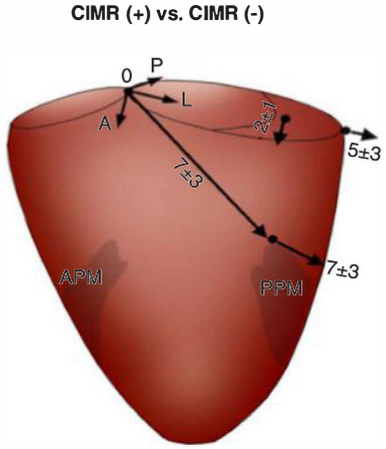

**FIGURE 34-8** Comparison of valvular geometric perturbations in the sheep that did [chronic ischemic mitral regurgitation—CIMR(+)] and did not [CIMR(−)] develop significant IMR 7 weeks after posterolateral myocardial infarction. Arrows indicate changes from baseline in the CIMR(+) group that were significantly different from changes in the CIMR(−) group. Annular enlargement and posterior papillary muscle displacement resulted in apical tethering of the posterior mitral leaflet associated with significant mitral regurgitation (P, posterior; L, lateral; A, apical; APM, anterior papillary muscle; PPM, posterior papillary muscle). (Reproduced from Tibayan FA, et al. *Circulation* 2003;108(Suppl 1):II116–II121.)

## SUMMARY

The mitral valve is a complex and dynamic structure that necessitates precise coordination of its constituents to achieve timely and efficient closure. Mitral pathophysiology may arise with dysfunction of the mitral annulus, mitral leaflets, the subvalvular apparatus, or a combination of these components resulting in mitral stenosis, regurgitation, or both. Although the pathophysiology of rheumatic mitral stenosis and degenerative mitral regurgitation has been well characterized, FMR and IMR continue to challenge scientists and surgeons alike. Further clinical and experimental studies are needed to better define the mechanisms of these vexing entities so that more effective reparative techniques can be developed and ultimately patient outcomes improved.

## MITRAL VALVE PATHOPHYSIOLOGY BOARD REVIEW QUESTIONS (CHAPTER 34)

1. Which of the following is true regarding mitral valve anatomy?
   A. The right fibrous trigone is part of the central fibrous body of the heart.
   B. The highest point of the mitral annulus is at the commissures.
   C. The mitral annulus increases in size during early systole.
   D. The posteromedial papillary muscle is larger and typically has one major head.
   E. Second-order chordae prevent leaflet prolapse.

2. Which is accurate according to Carpentier classification of the mitral valve?
   A. Type IIIb = excessive motion during systole
   B. Type I = isolated leaflet prolapse
   C. Type II = annular dilation
   D. Type IIIa = excessive motion during diastole
   E. Type IIIb = ischemic mitral insufficiency
3. Which is correct concerning degenerative mitral insufficiency?
   A. There is excessive fibroelastic tissue in the elderly.
   B. The spongy connective tissue can affect the chordae tendineae.
   C. The annulus is not involved.
   D. Most patients with prolapse eventually develop symptoms.
   E. Chordal rupture in older patients is almost always associated with combined anterior and posterior leaflet pathology.
4. Which is true regarding IMR?
   A. Sphericity does not accompany recurrent MR after ventricular reduction surgery.
   B. IMR is solely dependent on global LV dilation.
   C. An anterior infarction produces substantially reduced ejection fraction compared with an inferior infarction.
   D. A small posterolateral infarction has little effect on the subvalvar apparatus.
   E. Reverse remodeling is more predictable if the LV exceeds 65 mm.
5. Which is correct in IMR?
   A. There is decreased motion of the lateral annulus.
   B. Isolated papillary muscle dysfunction typically causes substantial MR.
   C. Diastolic dysfunction of the inferior wall is the prerequisite lesion for clinical IMR.
   D. IMR results in decreased coaptation depth.
   E. Valvular tenting is not present in IMR.

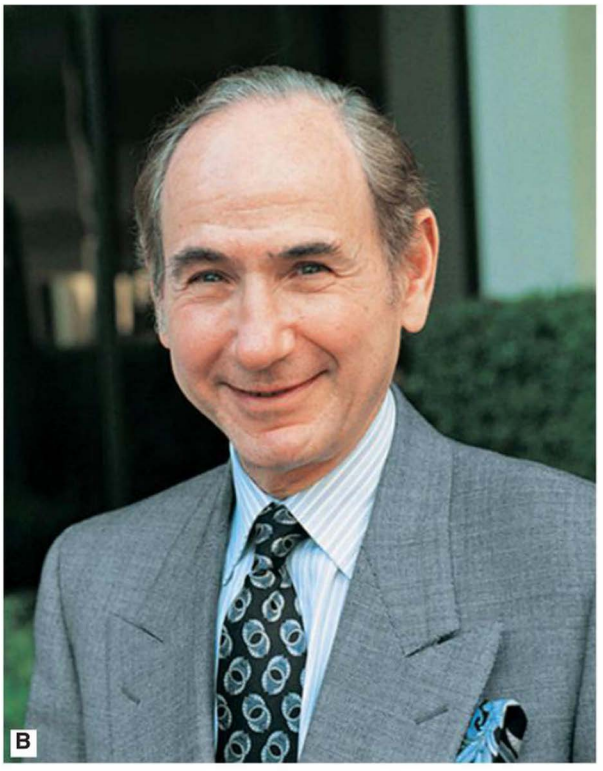
## ANSWERS

1. **Answer: A.** The right fibrous trigone is part of the central fibrous body of the heart. The commissures are the lowest point of the annulus. The mitral annulus decreases rapidly in size during early systole. The anterolateral papillary muscle is larger and typically has one major head. First-order chordae prevent leaflet prolapse.
2. **Answer: E.** The classification system is as follows: type I = normal leaflet motion, type II = leaflet prolapse or excessive motion, type III = restricted leaflet motion. Type IIIa = restriction during diastole, type IIIb = restricted during systole.
3. **Answer: B.** The spongy connective tissue can affect the chordae tendineae in addition to the valve leaflets. There is fibroelastic deficiency in the elderly. The annulus is commonly involved, becoming thickened and dilated. Most patients with isolated prolapse will not develop symptoms. Chordal rupture in older patients is usually associated with P2 prolapse; combined leaflet pathology is least common.
4. **Answer: C.** An anterior infarction produces greater LV and mitral annular dilation and depresses LV function more than an inferior infarction. Sphericity does accompany recurrent MR after ventricular reduction surgery. IMR is not dependent on global LV dilation but rather on a localized LV insult. A small posterolateral infarction can have significant effect on the subvalvar apparatus. Reverse remodeling is more predictable if the LV is smaller than 65 mm.
5. **Answer: A.** The lateral annulus exhibits decreased motion in IMR. Isolated papillary muscle dysfunction does not result in significant MR. Systolic dysfunction of the interior wall is the prerequisite lesion for IMR. IMR results in increased depth of coaptation, and valvular tenting is an important clinical predictor of effective regurgitant orifice.

# 35 Mitral Valve Replacement

*Stephen J. Huddleston*
*David D. Yuh*

**KEY CONCEPTS**



- Prosthetic valve design
  - Design of both mechanical and bioprosthetic valves has continued to evolve since the invention of the first valve to improve flow dynamics, reliability, and durability, while minimizing thrombogenicity and avoiding structural valve dysfunction (SVD).
- Indications
  - Mitral valve (MV) surgery is recommended for symptomatic acute severe mitral regurgitation (MR), chronic severe MR with New York Heart Association (NYHA) class II, III, or IV symptoms and no severe left ventricular (LV) dysfunction, and asymptomatic patients with mild-to-moderate LV dysfunction and severe MR. MV surgery is reasonable for asymptomatic severe MR in some cases. Mitral replacement in the setting of MR should be performed when repair is not possible or the functional result would be inadequate.
  - The indications for MV replacement in mitral stenosis are the following: (1) moderate (mean valve area ≤1.5 $cm^2$) or severe MS (mean valve area ≤1.0 $cm^2$) and NYHA functional class III or IV symptoms if they are not candidates for percutaneous balloon valvotomy or MV repair; and (2) severe MS with moderate-to-severe MR in symptomatic patients. MV replacement may be indicated for patients with severe MS with pulmonary hypertension and NYHA class I or II symptoms.
- Treatment (surgical)
  - The choice of prosthetic valve type is rooted in an understanding of valve features that determine thrombogenicity (the need for anticoagulation) and durability, as these factors relate to patient characteristics.
  - The most appropriate surgical approach to the MV is determined by patient characteristics and surgeon expertise. Typically, a median sternotomy, right thoracotomy, or mini right thoracotomy is employed. Aortic or femoral arterial cannulation and bicaval or femoral venous cannulation is performed depending on the incision. Venting may be performed through the aortic root and left atrium or left ventricle across the valve, and cardioplegia is given antegrade and retrograde. The valve may be exposed through a transverse incision in the left atrium or through a transseptal approach.
  - The chordal sparing technique of MV replacement improves LV function and survival. Valve stitches may be everting or noneverting.
  - Warfarin therapy with a goal INR of 2.5 to 3.5 is indicated after MV replacement with a mechanical prosthesis. Early anticoagulation for patients with bioprosthetic MVs is controversial.
- Outcomes/prognosis
  - MV replacement can be performed with outstanding efficacy, and risk is proportional to patient and surgical risk factors that can be assessed using well-established risk scoring systems. Acute surgical complications typically arise from problems with cardiopulmonary bypass or a combination of technical mistakes and patient factors. Late complications are rare and usually include prosthetic valvular endocarditis, thrombosis/anticoagulation, or SVD.

## INTRODUCTION

### History of Mitral Valve Replacement

The advent of cardiopulmonary bypass in 1953 opened the door for open cardiac surgery, but the first mitral valve (MV) replacement was not performed until 1959 at the National Heart Institute by Nina Starr Braunwald (Fig. 35-1A), the first woman to perform cardiac surgery.[1] Modeling anatomy, she designed the valve using flexible polyurethane with Teflon chordae. The patient was discharged from the hospital and did well clinically for several months. However, Albert Starr (Fig. 35-1B), a cardiac surgeon in Portland, OR, and Miles "Lowell" Edwards (Fig. 35-1C), an engineer in California,

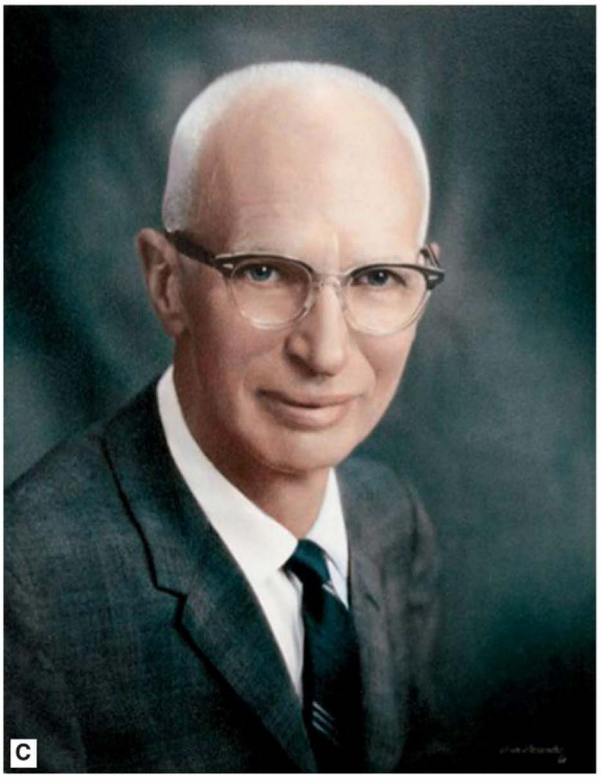


**FIGURE 35-1** Nina Starr Braunwald (**A**), the first surgeon to perform mitral valve replacement (**A**: Courtesy of the National Library of Medicine). Albert Starr (**B**) and Lowell Edwards (**C**) designed the caged-ball Starr–Edwards mechanical valve, which was the standard mechanical mitral valve for the first decade of mitral valve replacement (**B, C**: Reproduced with permission from Edwards Lifesciences, Irvine, California).

abandoned the approach of mimicking the native valve structure and instead focused on valve function to develop a more hemodynamically consistent and durable valve made from a silastic ball contained within a wire cage a rising from the valve housing.[2] This design debuted amidst a plethora of unique and distinct valve designs and revolutionized valve replacement, remaining the gold standard for MV replacement for much of that decade.

In pursuit of better hemodynamics and reduced thrombogenicity, the search for the perfect valve led to the development of other types of mechanical valves.[3] Tilting disk valves were introduced by Jura Wada in 1966 (Wada hingeless) and by C. Walt Lillehei and Robert Kaster in 1967 (Lillihei–Kaster). Viking Björk worked with the Shiley laboratories to develop the Björk–Shiley tilting disk valve that gained widespread application in the 1970s. Unfortunately, this valve had a propensity for thrombosis. After the disk design was changed to decrease thrombogenicity, the struts became susceptible to fracture. The valve was subsequently taken off of the market and many were removed from patients. The Medtronic-Hall tilting disk valve introduced in 1977 was the most commonly used tilting disk valve until it was recently taken off of the market in the United States. The most commonly used mechanical valve in the world today is the St. Jude mechanical bileaflet valve first introduced in 1977.

Driven by the problem of thrombogenicity of mechanical valves, work on bioprosthetic valves yielded the Carpentier and Hancock porcine xenografts in 1969,[4,5] and Marian Ionescu introduced a glutaraldehyde-fixed bovine pericardial valve in 1971.[6] These valves had promising early success, but structural valve dysfunction (SVD) was soon recognized to be a common complication, especially in younger patients. Further modification in the design and development of bioprosthetic valves has led to somewhat improved hemodynamics and durability, but SVD remains an obstacle to the use of these valves, especially in younger patients.

## INDICATIONS FOR REPLACEMENT VERSUS REPAIR

### Mitral Regurgitation

Because of improvements in MV repair techniques, repair of acquired mitral regurgitation (MR) is now usually feasible and durable, with improved left ventricular (LV) function, operative mortality, and long-term survival compared to MV replacement.[7] When repair is possible, survival is clearly better than with replacement if the MR is due to rheumatic, mixed, or degenerative disease, although the benefit of mitral surgery in ischemic MR is not as clear.[8] According to the American College of Cardiology/American Heart Association (ACC/AHA) Guidelines, mitral surgery is recommended for symptomatic acute severe MR, chronic severe MR with New York Heart Association (NYHA) class II, III, or IV symptoms and no severe LV dysfunction, and asymptomatic patients with mild-to-moderate LV dysfunction and severe MR.[9] Level II evidence suggests that MV surgery is reasonable for asymptomatic severe MR in some instances. The primary indication for mitral replacement in the setting of MR is when repair is not possible or the functional result would be inadequate. This may be due to valve pathology that prohibits repair, a failed attempt at repair, or surgeon experience. Pathologic and anatomic factors that may make replacement preferable to repair include rheumatic MR, the presence of calcific deposits, and shortened chordae or papillary muscles. In patients with endocarditis, destruction of the valve annulus, leaflets, chordae, or papillary muscles may preclude repair. The management of mitral valvular endocarditis is discussed in detail in Chapter 38, but repair is generally preferable to replacement when possible, although destruction of the valve apparatus may make repair impossible.[10]

### Mitral Stenosis

As opposed to MR, acquired mitral stenosis (MS), usually due to rheumatic disease, more often requires replacement because the pathologic effects on the valve apparatus are not amenable to repair. According to the ACC/AHA Guidelines, the indications for MV replacement in MS are the following: (1) moderate (mean valve area $\leq$1.5 cm$^2$) or severe MS (mean valve area $\leq$1.0 cm$^2$) and NYHA functional class III or IV symptoms if they are not candidates for percutaneous balloon valvotomy or MV repair; and (2) severe MS with moderate–severe MR in symptomatic patients. Some evidence supports MV replacement in patients with severe MS with pulmonary hypertension and NYHA class I or II symptoms.[9] Retrospective data suggest that the outcome with replacement for MS is better than with MV commissurotomy and valvuloplasty.[11]

## CHOICE OF VALVE TYPE

### Hemodynamic Evaluation of Prosthetic Valves

The perfect valve remains elusive, but several characteristics define the ideal valve:

- Minimal pressure drop
- Trivial regurgitation
- Minimal turbulence and stasis
- Absence of shear stress
- Lifelong durability
- Biologically inert
- Negligible thrombogenicity

All of these characteristics are related to valve hemodynamics to varying degrees. For example, greater turbulence and stagnation can contribute to thrombogenicity and shear stress can lead to hemolysis. These forces can damage tissue

valves and contribute to calcification of all valve types and SVD of bioprosthetic valves. Therefore, a basic understanding of the hemodynamic assessment of prosthetic valves is fundamental to understanding the evolution and comparison of different types of prosthetic valves.[3,12,13] The normal valve area of the MV is 4 to 6 $cm^2$. The prosthetic valve housing, stent, and any other components that are within the housing decrease the true cross-sectional valve area through which blood must flow, defined as the effective orifice area (EOA). Therefore, the functional orifice of the valve, the EOA, is less than the geometric cross-sectional area of both the native annulus and the housing, and this will confer an inherent resistance and pressure gradient. The EOA may be determined by the Gorlin formula (derived from catheterization data and a hydraulic formula) or by the continuity equation, derived from acquired Doppler data.

These formulas are useful in comparing different valves in the laboratory. In the clinical setting, replacing a valve with an undersized prosthesis and a relatively small EOA relative to the patient size, also known as patient–prosthesis mismatch (PPM), is an area of controversy. One recent retrospective analysis from a single institution found that PPM was associated with recurrent congestive heart failure, postoperative pulmonary hypertension, and decreased survival after MV replacement.[14] Another large retrospective study found that PPM predicted higher mortality at 6 and 12 years after MV replacement.[15] However, no prospective data correlate EOA–patient size mismatch with long-term morbidity and mortality.

Another important parameter in evaluating hemodynamic function of prosthetic valves is the performance index, the ratio of the EOA to the sewing ring of the valve. The performance index is a surrogate measure for how efficiently the valve employs the total geometric area.

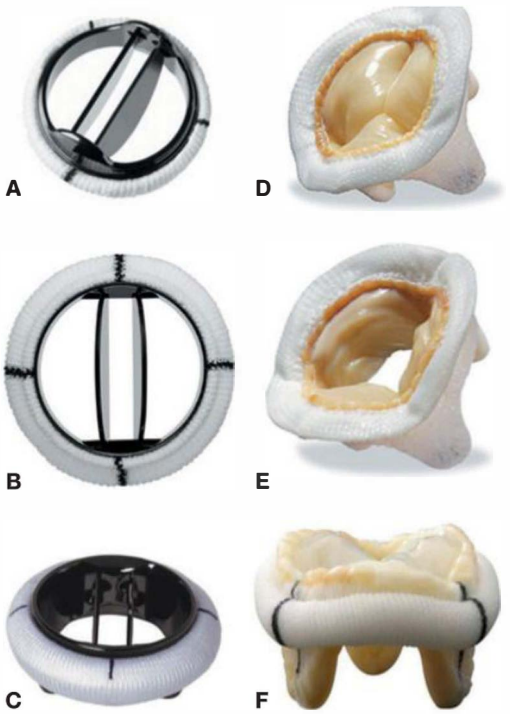

**FIGURE 35-2** Commonly used mechanical (**A–C**) and bioprosthetic (**D–F**) valves include the St. Jude mechanical (**A**: Permission to reproduce this image granted by St. Jude Medical, Inc.), Medtronic ATS Open Pivot Standard (**B**: Image reproduced with permission from Medtronic, Inc. Copyright Medtronic, Inc.), and On-X Mitral Standard (**C**: Image reproduced with permission from On-X Life Technologies, Inc.). Commonly used bioprosthetic valves include the Medtronic Hancock II (**D**: Image reproduced with permission from Medtronic, Inc. Copyright Medtronic, Inc.) and Mosaic (**E**: Image reproduced with permission from Medtronic, Inc. Copyright Medtronic, Inc.), as well as the St. Jude Biocor mitral valve (**F**: Permission to reproduce this image granted by St. Jude Medical, Inc.).

## Prosthetic Valve Types

Prosthetic valves are classified as either mechanical or bioprosthetic. Historically, the types of mechanical valves are caged ball, tilting disk, and bileaflet valves, although only bileaflet valves are currently available in the United States. These include the St. Jude mechanical (Fig. 35-2A), Sorin mechanical bileaflet, Medtronic ATS Open Pivot (Fig. 35-2B), and On-X Mitral Standard (Fig. 35-2C). Although both stented and stentless bioprosthetic valves have been used for MV replacement,[16] long-term follow-up is only available for stented bioprosthetic valves in the mitral position. Currently available bioprosthetic valves in the United States include the Carpentier–Edwards Perimount Magna pericardial bioprosthetic valve, Medtronic Hancock II (Fig. 35-2D) and Mosaic (Fig. 35-2E), as well as the St. Jude Epic mitral bioprosthetic valve (Fig. 35-2F). Homograft valves are not widely used for MV replacement. More than 50 different prosthetic valves have been introduced in the last 60 years. Unfortunately, insufficient data comparing different prosthetic valves in a prospective, randomized fashion exist to support the use of one type of valve over another. The individual characteristics of many of the different valves have been reviewed elsewhere.[3,17]

### MECHANICAL VERSUS BIOPROSTHETIC VALVES

Both patient and valve-related factors enter into the decision of whether to use a mechanical or a bioprosthetic valve.[17–19] Typically, mechanical valves have greater durability; however, they require lifelong anticoagulation. Bioprosthetic valves, on the other hand, are prone to SVD, but they are less thrombogenic and do not require anticoagulation. Hence, younger patients (<65–70 years old) are usually best served by a mechanical valve in order to avoid a reoperation for replacement of the bioprosthetic valve. However, patients who have contraindications to anticoagulation cannot have a mechanical valve. For example, women of child-bearing age who wish to conceive should

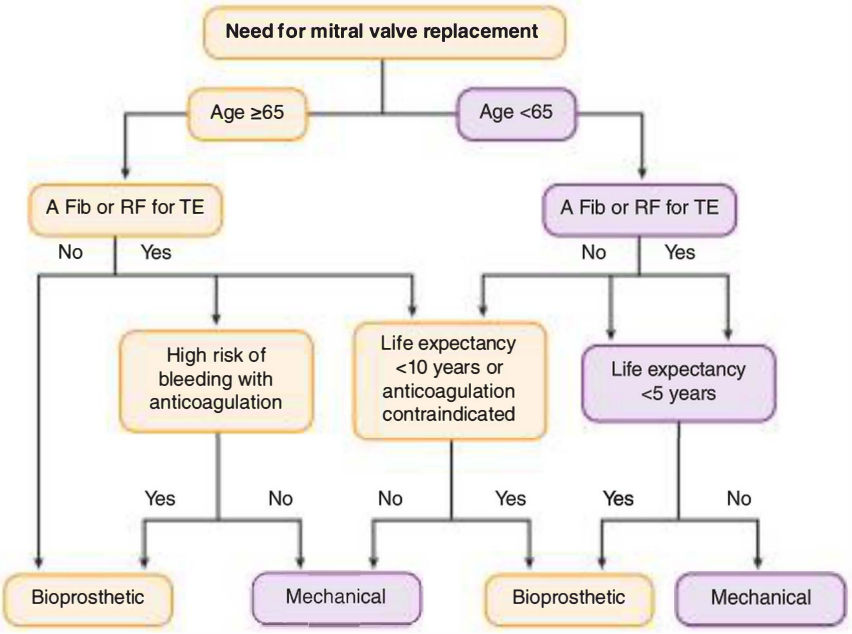

**FIGURE 35-3** An algorithm for the selection of mechanical versus bioprosthetic valves. A Fib, atrial fibrillation; RF, risk factor; TE, thromboembolism.

receive a bioprosthetic valve, and then after they are no longer planning on becoming pregnant, can undergo reoperation and replacement with a mechanical valve. Patients who are likely to be noncompliant with anticoagulation should also receive bioprosthetic valves. A patient at higher risk for bleeding complications with anticoagulation should receive a bioprosthetic valve. Alternatively, if a patient already has another indication for anticoagulation, such as atrial fibrillation, a mechanical valve does not present any additional risk. However, an older patient may be at increased risk of hemorrhagic complications, so a bioprosthetic valve may be indicated. Bioprosthetic valves may be sufficient for young patients with reduced longevity such as recalcitrant intravenous drug abusers and patients on permanent hemodialysis. Technical factors must also be considered, such as a small LV cavity that may not accommodate the stents of a bioprosthetic valve. An algorithm for selection of a prosthetic valve is presented in Figure 35-3. Clearly, the decision of whether a mechanical or bioprosthetic valve should be used is complex and should involve the patient, the cardiologist, and the cardiac surgeon.

# SURGICAL TECHNIQUE

## Surgical Approach

The MV may be approached through a median sternotomy, a right thoracotomy, an upper mini-sternotomy, a mini right thoracotomy, or robotically. The most appropriate incision or approach depends on patient factors such as previous operations, surgeon experience, and the need for combination with other procedures such as coronary artery bypass or aortic valve replacement. A median sternotomy is required when coronary artery bypass is performed in addition to MV replacement or in combined aortic valve and MV replacement. A right lateral, anterolateral, or posterolateral thoracotomy through the fourth intercostal space is particularly useful in a patient who has had a previous sternotomy and who does not require coronary artery bypass or aortic surgery. Minimally invasive MV surgery is gaining acceptance, and with appropriate surgeon experience, the MV may be exposed through a mini right thoracotomy with reduced blood loss and fewer transfusions.[20] The mini upper sternotomy has been described for mitral surgery but is much less commonly used.

## Combined Procedures

When MV replacement is combined with other procedures, the order of procedures is of critical importance so as to prevent the devastating complication of atrioventricular groove dissociation. If MV replacement is combined with coronary artery bypass, the distal anastomoses should be performed before valve replacement. Hemostasis of the distal anastomoses should be confirmed before MV replacement in order to avoid lifting the heart afterward, since this may cause an atrioventricular groove tear. If MV replacement is performed in combination with aortic valve replacement, the aortic valve should be excised first, followed by sequential replacement of the mitral and aortic valves.

## Cannulation and Cardiopulmonary Bypass Strategy

The strategy for arterial and venous cannulation depends on the surgical approach. If MV replacement is performed through a sternotomy, the aorta will be cannulated and bicaval venous cannulation is employed with a right angle metal tip cannula placed in the superior vena cava and a straight or right angle metal tip cannula in the inferior vena cava. If a standard right thoracotomy is used, the venous cannulation may be central or peripheral depending on the exposure, and femoral arterial cannulation is used. If the approach is through a mini right thoracotomy, cannulation of the right internal jugular and right femoral vein is performed. Caval snares should be placed for inflow occlusion, especially if the transseptal approach to the MV is anticipated. In a reoperation, femoral or axillary arterial cannulation, in addition to femoral venous cannulation, may be safer. If a right minithoracotomy or robotic approach is used, femoral arterial cannulation is required. MV replacement usually requires cardioplegic arrest, achieved through antegrade and/or retrograde infusion of cardioplegia. Moderate hypothermia and topical cold saline or ice provides additional myocardial protection. In certain situations such as reoperative mitral surgery after coronary bypass with an internal mammary graft, ventricular fibrillatory arrest may be employed. Venting may be performed through the aortic root or with a LV vent temporarily placed across the prosthetic valve after completion of the replacement; this vent is removed just prior to closure of the atriotomy.

## Exposure of the Mitral Valve

After developing Sondergaard's groove, a transverse left atriotomy is placed posterior to the interatrial sulcus close to the MV. When the sternum is deep or the left atrium is small, several techniques have been described to optimize exposure.[21] As described by Brawley,[22] the right atrium may be incised from the right atrial appendage toward the inferior vena cava and then the atrial septum can be incised at the inferior aspect of the fossa ovalis and the incision is extended superiorly to meet the right atriotomy. If necessary, the superior vena cava may be transected for additional exposure. The transseptal approach has also been described by Khonsari using a transverse incision through the atria extending from the right atrial appendage, across the atrial septum and over the roof of the left atrium toward the right superior pulmonary vein. The atrial septal incision is extended posteriorly and laterally into the fossa ovalis. Care must be taken when dividing the atrial septum to avoid injury to the bundle of His.

## Technique of Replacement

The chordal sparing technique for MV replacement is preferable when possible because of the preservation of annuloventricular continuity and LV function with improved survival.[23,24] The extent of preservation of the subvalvular apparatus depends on the severity and pattern of disease. If possible, both the anterior and posterior leaflets with associated first- and second-order chordae should be preserved. This may involve preservation of the entire leaflet with imbrication and plication of the leaflet tissue to the annulus using the valve sutures. Alternatively, a portion of each leaflet is excised and then the remaining leaflet with the attached chordae is fixed to the annulus.

Several chordal sparing techniques have been described. The posterior leaflet may be preserved by excising a crescent-shaped portion of the valve, leaving a rim of leaflet along the posterior annulus and a rim of leaflet with the attached chordae (Fig. 35-4A). The leaflet rim with the attached chordae is then attached to the posterior annulus with the valve sutures. If the anterior leaflet can be preserved, the central portion of the leaflet without chordae is resected and the anterolateral and posteromedial aspects of the leaflet with the underlying chordae are preserved (Fig. 35-4A). In the technique described by David,[25] the residual portions of the anterior leaflet are then reattached to the annulus with the valve sutures. In the technique described by Nara,[26] the A1 and A3 portions of the anterior leaflet with the associated anterolateral and posteromedial chordae are attached to the mitral commissures with pledgeted 2-0 braided sutures (Fig. 35-4B). The anterior leaflet halves may also be transposed onto the posterior annulus as described by Fiekes. The anterior leaflet may be divided into "buttons" with the attached chordae[27] and these may be reattached anatomically to the anterior annulus (Khonsari I, Fig. 35-4C) or a central scallop of the anterior leaflet may be excised and the contiguous strip of the anterior leaflet that has been detached may be plicated to the anterior annulus with the valve sutures (Khonsari II, Fig. 35-4D) or with a running polypropylene suture. If the chordae are too fibrotic and foreshortened, they may be excised and artificial chordae may be constructed using 4-0 PTFE sutures placed between the papillary muscle heads and the annulus. In addition to maintaining LV function, preservation of the posterior leaflet and the associated subvalvular apparatus protects against atrioventicular groove separation and LV perforation.

The valve annulus is sized appropriately and interrupted, horizontal, everting, pledgeted mattress braided sutures are placed in the annulus (Fig. 35-4A–D). If the annulus is calcified or when using a bioprosthetic valve, nonevverting pledgeted mattress sutures may be used (Fig. 35-5). If the annulus is severely calcified, extensive debridement and reconstruction with an autologous pericardial or bovine pericardial patch may be required. Care must be taken during placement of sutures in the valve annulus to avoid injury to surrounding structures including the left circumflex artery, the coronary sinus, the left atrial appendage, the aortic valve and LV outflow tract (LVOT), the anterior mitral curtain, and the atrioventricular node. Also, care must be taken to avoid capturing the valve stent in one of

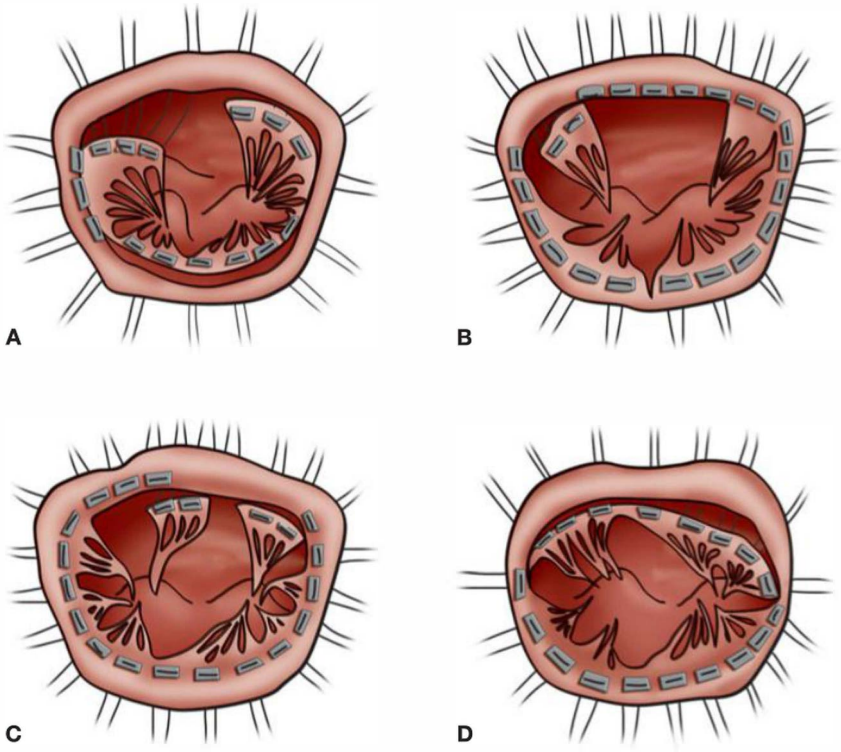

**FIGURE 35-4** Chordal sparing mitral valve replacement techniques as described by David (**A**), Nara (**B**), and Khonsari (I and II portrayed in **C** and **D**, respectively) using noneverting valve suture placement. (Illustration created by artist Shelley C. Griffin.)

the annular stitches. After the prosthetic valve is sutured in place, the leaflet motion should be evaluated to ensure that there is no interference with LV function and the LVOT is not compromised. An LV vent may be placed through the prosthetic valve before closing the atriotomy. Rewarming is completed and conventional de-airing maneuvers are performed. After leaving volume in the heart, the prosthetic valve function, LVOT, and completeness of de-airing are evaluated by transesophageal echocardiography (TEE). If there is no significant LVOT obstruction, mitral valvular regurgitation, or paravalvular leak, the patient is weaned from bypass.

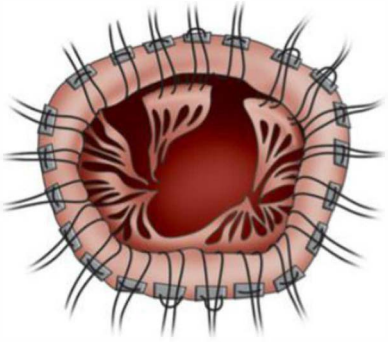

**FIGURE 35-5** Everting mattress sutures for valve fixation. (Illustration created by artist Shelley C. Griffin.)

## POSTOPERATIVE CARE AND OUTCOMES

### Anticoagulation

Warfarin therapy with a goal INR of 2.5 to 3.5 is indicated after MV replacement with a mechanical prosthesis.[9] Although the risk of thromboemboli remains 1 to 2 percent per year even with warfarin, it is much less than without. The risk of thromboembolism is higher with mechanical valves in the mitral position than in the aortic position, so the INR goal is higher for mechanical MVs than for aortic mechanical prosthetic valves.[9,28] The use of unfractionated heparin as a bridge to warfarin anticoagulation is controversial. If a patient with a mechanical valve has additional risk factors, aspirin 81 to 325 mg daily should be given in addition to warfarin. The On-X valve was found to have a low rate of thromboembolism even in the absence of or inadequate

anticoagulation,[29] and an ongoing trial is investigating outcomes with an INR of 2.0 to 2.5 plus aspirin 81 mg/day.

With a bioprosthetic valve in the mitral position, the risk of thromboemboli is only about 0.7 percent per year, although the risk has been reported to be higher during the first 3 months after replacement.[30] Anticoagulation is controversial for bioprosthetic MV replacements, and while some surgeons advocate warfarin anticoagulation for the first 3 months postoperatively, others do not anticoagulate unless there is another indication such as atrial fibrillation, previous thromboembolism, LV dysfunction (ejection fraction less than 30 percent), or a hypercoaguable condition.

Whenever a patient with a mechanical MV or a bioprosthetic valve with other risk factors for thromboemboli requires noncardiac surgery, an invasive procedure, or a dental procedure, the warfarin should be held and intravenous heparin should be started when the INR drops below 2.0.[9] The heparin is held for 4 to 6 h before the procedure and restarted after the procedure when the risk of bleeding is thought to be acceptably low. The warfarin is then restarted and the heparin is continued until the INR reaches 2.0. In an emergency, fresh frozen plasma may be given to correct the INR rapidly.

## OUTCOMES AND COMPLICATIONS

More than 90 percent of patients who undergo MV replacement should experience a functional improvement in outcome with significant resolution of heart failure symptoms. The morbidity and in-hospital mortality for MV replacement depends on patient demographics, risk factors, previous cardiovascular history, preoperative condition, and operative status (e.g., first time versus reoperation). This risk may be assessed using data from the Society for Thoracic Surgery Database or the European Risk System in Cardiac Operations.[31,32] Because these tools depend on frequent calibration, dependent on multiple dynamic factors, they must continuously be updated to maintain accuracy. Predictors of a poor outcome include advanced patient age, poor functional class, coronary artery disease, reoperative status, and emergency operations. Common causes of early operative mortality include stroke, myocardial infarction, respiratory failure, multisystem organ failure, and infection. Stroke may still occur later, and other late causes of postoperative mortality include persistent heart failure and complications related to thromboemboli. The risk of hemorrhage due to anticoagulation is proportional to the degree of anticoagulation.

The outcome of mechanical valve replacement has improved dramatically with adoption of chordal sparing techniques and preservation of ventriculoannular continuity. Conversely, technical misadventures can lead to devastating complications. Paravalvular leak will lead to persistent MR with heart failure and possibly hemolysis. If a paravalvular leak is detected on intraoperative TEE, cardiopulmonary bypass should be reinstituted and the cause corrected.

LV rupture is an uncommon but often fatal complication. In a retrospective analysis by Deniz and colleagues, the incidence of posterior ventricular rupture after MV replacement was 0.8 percent, and risk factors included age greater than 60, female gender, reoperation, and resection of the posterior leaflet.[33] None of the patients in that series who had preservation of the posterior leaflet had LV rupture. LV rupture may occur at the level of the annulus, at the base of an excised papillary muscle, or between the papillary muscle and the annulus. Excessive traction on the annulus and overzealous debridement of annular calcifications should be avoided in order to minimize the risk of LV rupture. After valve replacement, lifting of the heart should be avoided to prevent LV rupture. If LV rupture occurs, the patient should be placed back on cardiopulmonary bypass immediately and the prosthetic valve should be removed in order to gain access to the LV rupture. A bovine pericardial patch is sutured to the ventricular endocardium and used to reconstruct the annulus. After the prosthetic valve is resutured in place using pledgeted sutures, the atrial edge of the bovine pericardial patch is sutured to the atrial endocardium. Atrioventricular groove hematoma or disruption is another rare complication similar to LV rupture often related to extensive debridement and decalcification of the annulus and posterior leaflet.

In addition to thromboembolic and bleeding complications due to anticoagulation, several other valve-related complications may occur after MV replacement. The risk of SVD is inversely proportional to the age of the patient (especially <65 years of age) and is more common in the mitral than in the aortic position.[34,35] SVD begins at about 5 years after MV replacement, and the incidence increases significantly after 10 years. The only treatment for SVD is reoperation with re-replacement of the valve prosthesis. Transcatheter valve-in-valve implantation has been reported for the treatment of SVD of bioprosthetic valves in the mitral position.[36]

Valve thrombosis in the absence of infection with obstruction of flow through the valve or interference with valve function has an incidence of 0.5 percent after MV replacement.[37] The presentation of valve thrombosis ranges from subtle findings to cardiogenic shock. Traditionally, valve thrombosis was an indication for emergent surgical thrombectomy with possible replacement of the prosthetic valve, but thrombolysis is increasingly considered the first-line treatment, although embolic complications are a concern.

The risk of prosthetic valvular endocarditis (PVE) is highest in the first 3 months after replacement and is slightly greater for mechanical than for bioprosthetic valves. The risk of early PVE is about 1 percent in the first 12 months, and the risk of late PVE is 0.2 to 0.35 percent per patient-year. Bacteremia or contamination leading to PVE may occur intraoperatively or from placement of intravenous catheters, indwelling urinary catheters, invasive procedures, and wound infections.

## MITRAL VALVE REPLACEMENT BOARD REVIEW QUESTIONS (CHAPTER 35)

1. MV replacement is indicated for:
   A. A 65-year-old man with dyspnea, severe MR, and posterior on echocardiography
   B. A 25-year-old man with recent intravenous drug abuse and mitral valvular endocarditis with an anterior leaflet vegetation greater than 1.5 cm in greatest dimension
   C. A 55-year-old woman with dyspnea with minimal activity and moderate MS with thickening of the leaflets and severe fibrosis and shortening of the chordae that is not amenable to percutaneous mitral balloon valvuloplasty
   D. A 70-year-old man with 3-vessel coronary artery disease, a non-ST-segment elevation myocardial infarction and ischemic mitral regurgitation

2. A bioprosthetic valve is preferable to a mechanical valve for MV replacement for:
   A. A 45-year-old man with severe MR and mitral valvular endocarditis with a 9-mm vegetation on the anterior leaflet and peripheral emboli despite treatment with antibiotics
   B. A 35-year-old woman with rheumatic heart disease and severe MS who wishes to conceive
   C. A 60-year-old man with atrial fibrillation on warfarin anticoagulation and severe MS
   D. A 55-year-old woman with severe MS

3. When performing combined aortic valve replacement (AVR), MV replacement and 2-vessel coronary artery bypass with the left internal mammary artery to the left anterior descending artery and a saphenous vein graft to the obtuse marginal branch of the left circumflex artery, the correct order of procedures is:
   A. Excise aortic valve, MV replacement, aortic valve replacement, distal anastomoses, proximal anastomosis.
   B. Distal anastomoses, excise aortic valve, aortic valve replacement, MV replacement, proximal anastomosis.
   C. Distal anastomoses, MV replacement, excise aortic valve, aortic valve replacement, proximal anastomosis.
   D. Distal anastomoses, excise aortic valve, MV replacement, aortic valve replacement, proximal anastomosis.

4. The chordal sparing technique of MV replacement has:
   A. Reduced the incidence of postoperative thromboembolic complications
   B. Not improved survival after MV replacement
   C. Been associated with increased risk of left ventricular rupture when the posterior leaflet is preserved
   D. Been associated with improved left ventricular function compared to the nonchordal sparing technique.

5. The risk of thromboembolic complications after MV replacement is:
   A. Higher in mechanical prosthesis with anticoagulation than with mechanical AVR with anticoagulation
   B. Less with a mechanical valve with anticoagulation than with a bioprosthetic valve without anticoagulation
   C. Not affected by poor ventricular function with a left ventricular ejection fraction less than 30 percent
   D. Is negligible in a patient with a mechanical valve and warfarin anticoagulation

## ANSWERS

1. **Answer: C.** MV replacement is indicated for moderate MS with NYHA class III symptoms when percutaneous mitral balloon valvuloplasty is not an option. MR with posterior leaflet prolapse is often amenable to repair, as is mitral valvular endocarditis not responding to medical therapy. Ischemic mitral regurgitation often responds to MR and usually does not require MV replacement.
2. **Answer: B.** A bioprosthetic valve is appropriate in a woman of child-bearing age who wishes to conceive. After the woman is has completed child bearing, she can undergo reoperation for replacement with a mechanical valve with postoperative warfarin anticoagulation.
3. **Answer: D.** When performing combined AVR and MV replacement with coronary artery bypass, distal anastomoses should be performed first. Next the aortic valve should be excised, since this can disrupt the MV replacement if it was done before excision of the aortic valve. After replacing the MV, the heart should no longer be lifted to minimize the risk of posterior LV rupture. The aortic valve replacement is then performed and the proximal anastomosis is performed last after closure of the aortotomy.
4. **Answer: D.** The chordal sparing technique of MV replacement has no impact on the incidence of postoperative thromboembolic complications, but LV function and postoperative survival are both improved. The risk of LV rupture is less with preservation of the posterior leaflet and the chordal sparing technique.
5. **Answer: A.** The risk of thromboembolic complications after mechanical MV replacement with anticoagulation is higher than with mechanical AVR with anticoagulation. Thromboembolic complications occur in 1 to 2 percent of patients after mechanical MV replacement despite anticoagulation with a goal INR of 2.5 to 3.5, compared to 0.7 percent of patients with a bioprosthetic MV replacement. Low LV ejection fraction (<30 percent), atrial fibrillation, previous thromboembolism, and a hypercoagulable state increase the risk of thromboembolic complications and are indications for the addition of aspirin to warfarin anticoagulation.

# Mitral Valve Repair for Degenerative Disease

*Gurjyot Bajwa*
*Tomislav Mihaljevic*
*A. Marc Gillinov*

**KEY CONCEPTS**

- Advantages of repair vs replacement
  - Degenerative disease of the mitral valve is a surgically treatable entity, when repaired leading to improved quality of life and better long-term survival as opposed to replacement.
- Keys to repair
  - Condition of the mitral valve
  - Experience of the surgeon
- Repair techniques
  - Choice of repair depends on the site of prolapse.
  - Tailor repair to site and mechanism determined by perioperative echocardiogram
- Surgical approaches
  - Range from complete sternotomy to robotically assisted
  - Choice of approach should be tailored to valve pathology determined preoperatively.
  - Standard, reproducible repair techniques should be employed.
- Outcomes
  - Durability of repair is measured by freedom from reoperation and recurrence of MR.
  - Operative risk is less than 1 percent.
  - Long-term survival rates at 10, 15, and 20 years are 92, 76, and 48 percent, respectively

## ADVANTAGES OF MITRAL VALVE REPAIR OVER REPLACEMENT

It is well accepted that the majority of patients with degenerative mitral valve disease who require surgery will have an improved quality of life with less morbidity and better long-term survival with valve repair as opposed to replacement.[1] This is attributable primarily to prosthesis-related morbidity, including higher reoperation rates, greater risk of endocarditis, and the need for anticoagulation with mechanical valves. Anticoagulation is particularly problematic for young, active patients and women in the child-bearing age group.

Therefore, when feasible, repair is preferred to replacement. The two keys to repair feasibility are the condition of the mitral valve and the experience of the surgeon. In most cases, mitral valve repair is technically no more complex than valve replacement. Mastery of only a handful of repair techniques enables repair of more than 90 percent of degenerative valves. A successful mitral valvuloplasty for degenerative disease provides most patients with an extremely durable valve, with many patients remaining free of reoperation 30 years after valve repair.[2]

## REPAIR TECHNIQUES

The choice of repair technique for a given mitral valve depends upon the site of prolapse. We will present, in sequence, repair options for posterior, anterior, commissural, and bileaflet prolapse.

### Posterior Leaflet Prolapse

Approximately 75 percent of patients with mitral regurgitation (MR) caused by degenerative disease have isolated prolapse of the posterior leaflet, most commonly the P2 segment (middle scallop).[3] Several techniques have been developed to deal with this anatomical site of prolapse.

## QUADRANGULAR RESECTION

This is the classic technique for managing P2 prolapse, with or without a sliding repair.[4] The sliding repair was developed to reduce the risk of postrepair systolic anterior motion (SAM) in the setting of excessive leaflet tissue and/or a small, hyperdynamic left ventricle.[5] The classic quadrangular resection, which includes annular plication, is rarely employed today and has been largely replaced by a triangular resection technique. Similarly, a folding repair technique has replaced the sliding repair.

## TRIANGULAR RESECTION

In the patient with segmental posterior leaflet prolapse, MR is caused by lack of leaflet coaptation at the site of posterior chordal rupture or elongation. Hence, it is logical to target the free edge of the prolapsing or flail leaflet.[6,7] A triangular resection comprises resection of the localized prolapsed or flail segment, with incisions in the leaflet angled toward one another as the incisions approach the annular level. No annular plication sutures are necessary. This simplified resection technique is particularly useful in minimally invasive right thoracotomy or robotic approaches as it saves operative time. As with most mitral repairs, this repair is completed with placement of a posterior flexible annuloplasty band (Fig. 36-1).

## FOLDING PLASTY

The folding plasty technique is used to treat posterior leaflet prolapse when there is a high risk of SAM, replacing the sliding repair for this indication.[8] The prolapsing portion of the posterior leaflet is resected as for a quadrangular resection, leaving tall posterior leaflet remnants on either side (Fig. 36-2). A suture is passed through the midportion of the cut leaflet edge on each side, and this suture is then passed through the annulus at the midportion of the area of resection; this maneuver reduces the posterior leaflet height. If necessary, suture placement is modified to ensure that the leaflet remnants are of similar height. Leaflet tissue is then approximated to the annulus, closing the gap at the annular level and uniformly reducing the height of the posterior leaflet in this region. The leaflet edges are reapproximated centrally and an annuloplasty band completes the repair.

## ARTIFICIAL CHORDAE

There is growing enthusiasm for the use of artificial chordae to correct posterior leaflet prolapse. The chordae are constructed from ePTFE (Gore-Tex, W.L. Gore and Assoc, Flagstaff, AZ).

Two general chordal replacement techniques may be used. Chordal loops can be fashioned and affixed to a papillary muscle, creating multiple new chordae (loops) of the same length; usually this length is approximately 10 mm when treating posterior prolapse. Each of the chordal loops is attached to the free edge of the prolapsing leaflet with a figure-of-eight suture. The chordae are spaced on the leaflet edge at distances of 7 to 10 mm.[9,10] (Fig. 36-3)

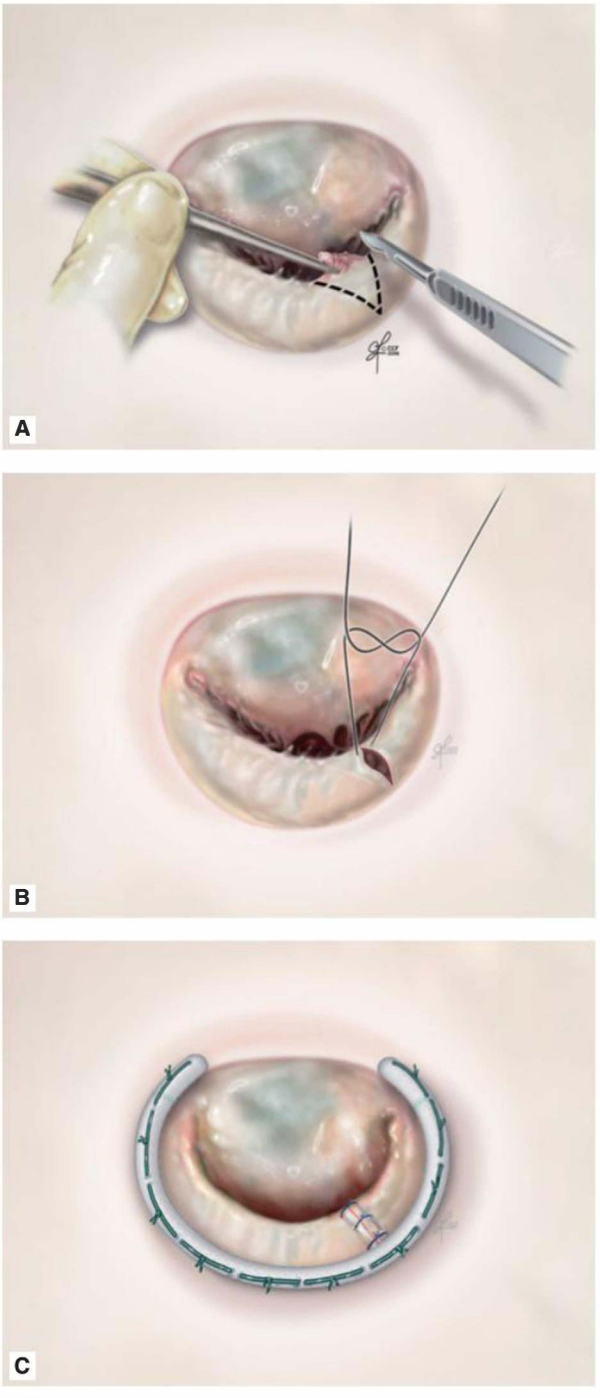

**FIGURE 36-1** Triangular resection. **A.** The prolapsing/flail segment of the posterior leaflet is identified and excised as a triangle. **B.** The leaflet edges are reapproximated. **C.** Annuloplasty completes the repair. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

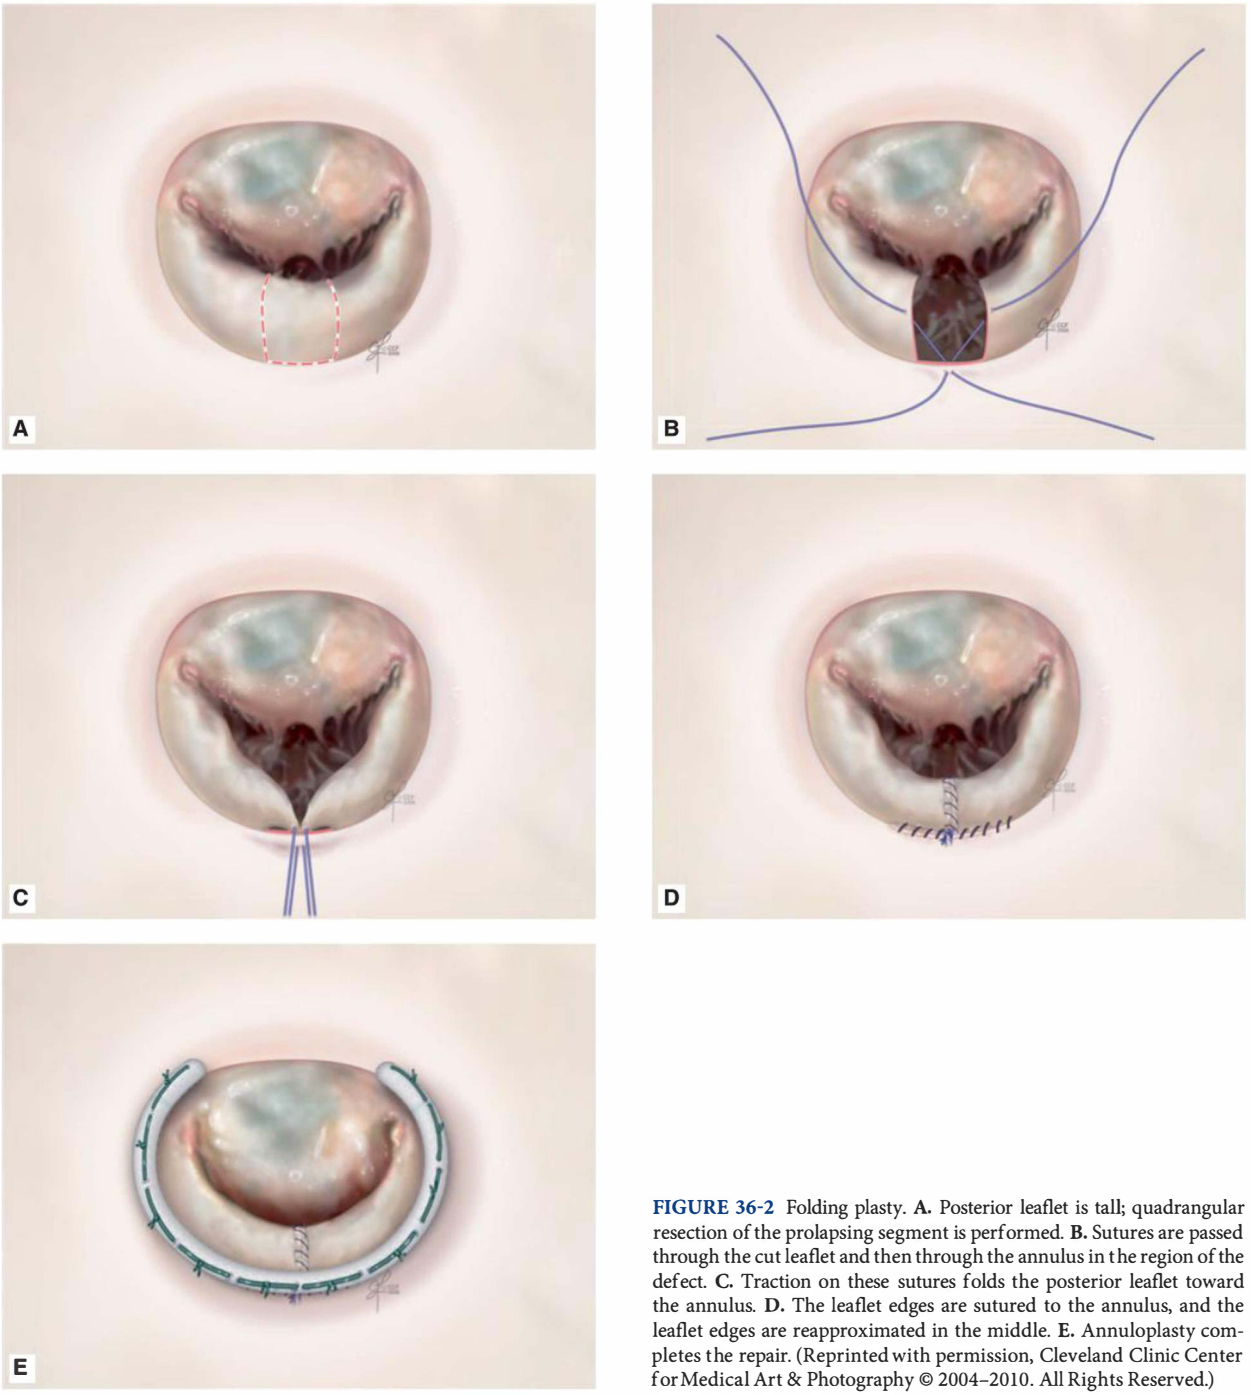

**FIGURE 36-2** Folding plasty. **A.** Posterior leaflet is tall; quadrangular resection of the prolapsing segment is performed. **B.** Sutures are passed through the cut leaflet and then through the annulus in the region of the defect. **C.** Traction on these sutures folds the posterior leaflet toward the annulus. **D.** The leaflet edges are sutured to the annulus, and the leaflet edges are reapproximated in the middle. **E.** Annuloplasty completes the repair. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

Alternatively, a figure-of-eight ePTFE suture is taken through the tip of a papillary muscle, and then each needle is brought up through the free edge of the leaflet twice, each time from the ventricular to the atrial side. The annuloplasty band is placed next. Then the ventricle is insufflated with saline and the chordae are adjusted to a length such that there is no leakage. Care is taken when tying the chordae at the leaflet edge, as excessive tension at tying will cause the chordae to be too short, resulting in leaflet restriction (Fig. 36-4).

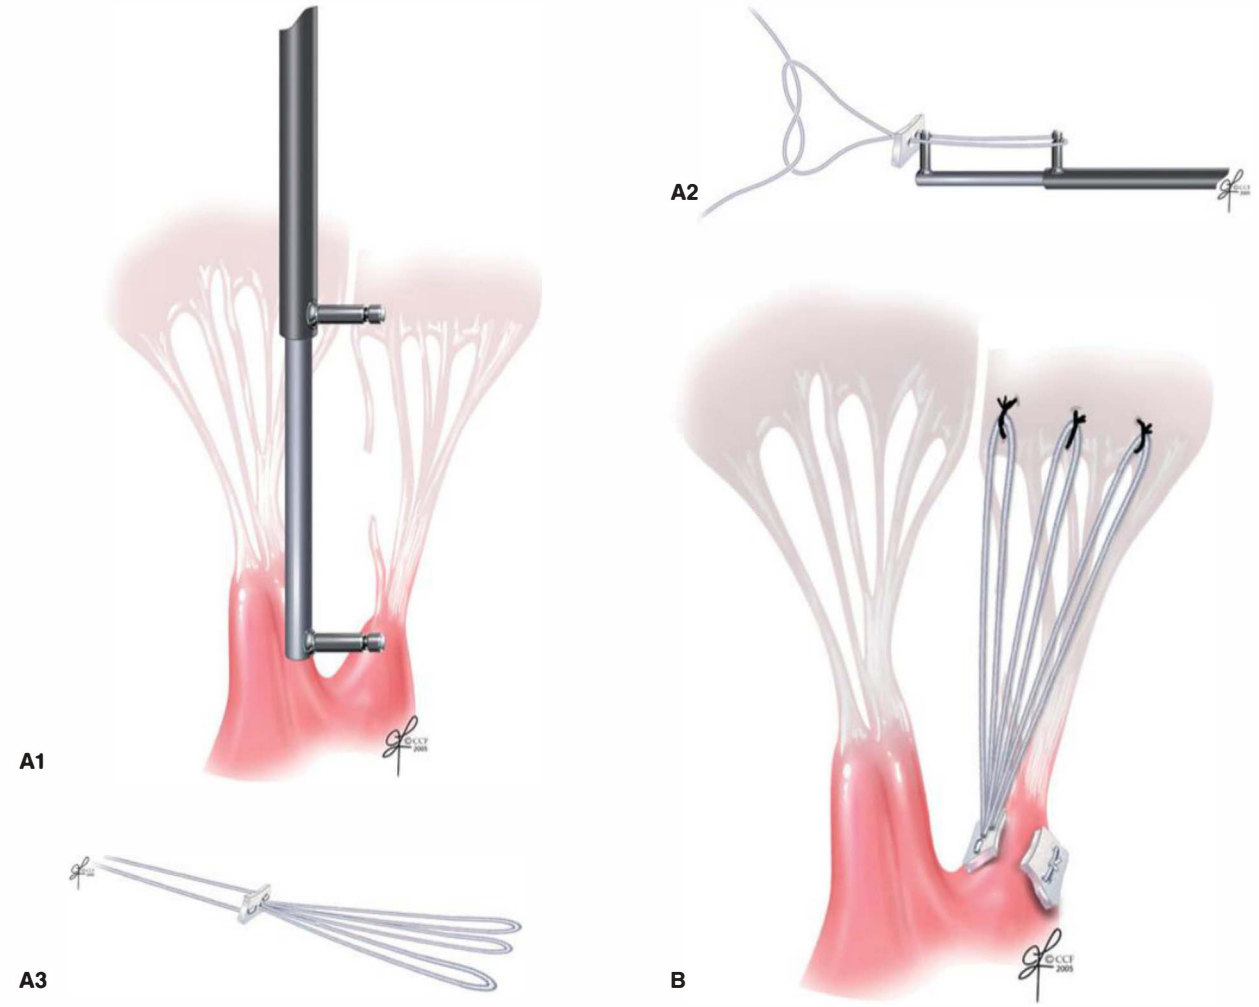

FIGURE 36-3 Creation of premeasured artificial chordae. **A.** Chordal loops are made after caliper measurement is taken. **B.** The loops are affixed to a papillary muscle and then individually to the free edge of the prolapsing segment of the leaflet. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

## Anterior Leaflet Prolapse

Anterior leaflet prolapse has traditionally posed a challenge for surgeons performing mitral valve repair. Repair techniques include artificial chordae, chordal transfer, commissuroplasty, and the Alfieri edge-to-edge repair. Freedom from reoperation after anterior leaflet repair has been inferior to that after posterior repair. There is no question that repair of P2 leaflet prolapse by posterior resection and annuloplasty is technically simpler than anterior leaflet repair. However, standardization of anterior repair through the use of artificial chordae provides a relatively simple and durable repair.

### ARTIFICIAL CHORDAE

The key challenge in using artificial chordae is the proper determination of chordal length; there are many techniques for estimating chordal length.[9,10] If chordal loops are used, the surgeon uses a caliper to measure the length of a normal chord from the head of the papillary muscle to the level of the annulus. Chordal loops of this length—usually 21 to 23 mm—are constructed, affixed to a papillary muscle and then to the free edge of the leaflet. Alternatively, the free-hand technique for chordal construction can be used. As with posterior leaflet prolapse, this involves a figure-of-eight ePTFE suture passed through the papillary muscle, followed by two passes through the free edge of the prolapsing leaflet, and tying the suture with the annuloplasty band in place and the ventricle filled with saline to assure valve competence.

### CHORDAL TRANSFER

This technique consists of excising a portion of the posterior leaflet with normal chordae and transferring it to

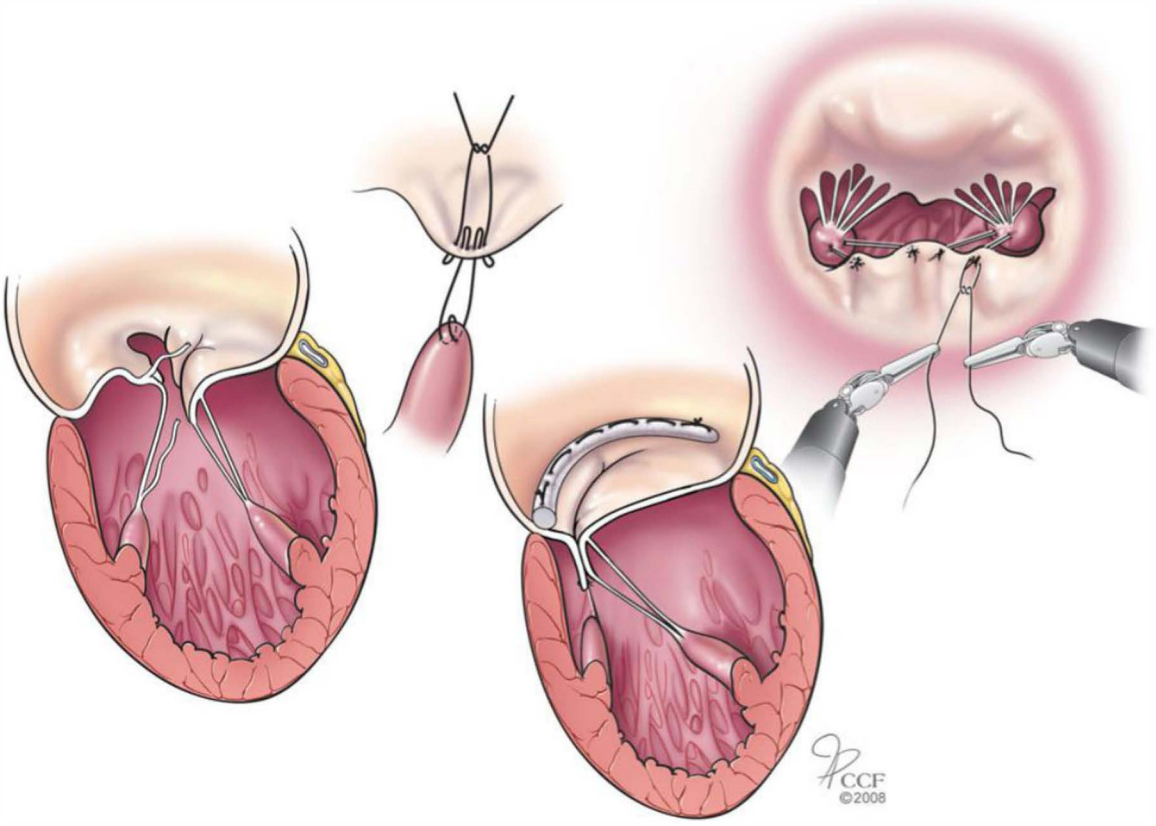

**FIGURE 36-4** Artificial chordae. Figure-of-eight-stitch through the papillary muscle, then through the free edge of the leaflet, with knots tied on the atrial aspect. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

support a portion of the anterior leaflet to which chordae have ruptured or elongated. Essentially, the posterior leaflet and its chords are "flipped over" to the anterior leaflet. The posterior leaflet is reconstructed in standard fashion and an annuloplasty band completes the repair (Fig. 36-5). The limitation of this technique is that it requires manipulation of a previously normal posterior leaflet in order to address anterior leaflet pathology. For this reason, we currently favor creation of artificial chordae to correct anterior leaflet prolapse.

### EDGE-TO-EDGE REPAIR

Described by Alfieri and coworkers, the edge-to-edge repair is the simplest maneuver for correction of prolapse.[11] With this technique, the prolapsing segment of the anterior leaflet is sutured to normal posterior leaflet directly opposite, ensuring coaptation and preventing prolapse. Sutures are taken several millimeters deep into the leaflet and span the entire region of prolapse. The suture line should not exceed 1 cm in length. Of note, the edge-to-edge technique can also be employed to manage posterior prolapse and bileaflet prolapse; however, it is rarely our primary repair technique for these pathologies.

## Commissural Prolapse

Commissuroplasty is a simple and reproducible technique for management of commissural prolapse involving the anterior, posterior, or both leaflets.[12] The edge of the prolapsing segment is sutured to the free edge of the opposite leaflet (Fig. 36-6). Care must be taken to avoid closing too much of the valve orifice. In addition, a relatively large annuloplasty band is employed to avoid mitral stenosis.

## Bileaflet Prolapse

Bileaflet prolapse is often a consequence of Barlow's disease. Management of this entity depends on valve pathology. Nearly all of these patients have excess leaflet tissue and annular dilatation. In many patients with bileaflet prolapse, the prolapse is asymmetrically distributed, with the predominant lesion being prolapse of the middle scallop of the posterior leaflet. This produces an anteriorly directed jet of MR. In such cases, mitral repair is most often achieved by a triangular resection of the P2 scallop. If the reconstituted leaflet height is extensive, a sliding repair or folding plasty is performed. A large annuloplasty ring completes the repair.

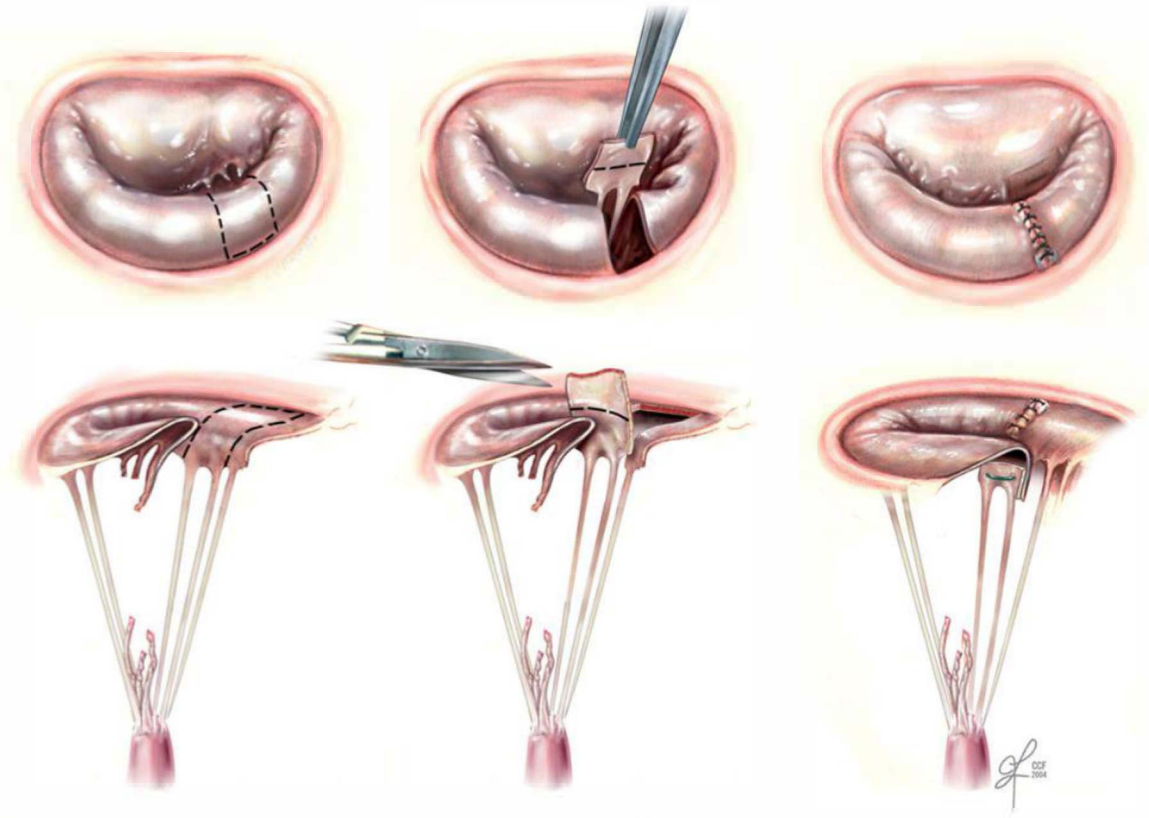

**FIGURE 36-5** Chordal transfer. A strip of posterior leaflet tissue with the attached normal chordae is transferred to the prolapsing free edge of the anterior leaflet. The posterior leaflet edges are reapproximated. Annuloplasty completes the repair. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

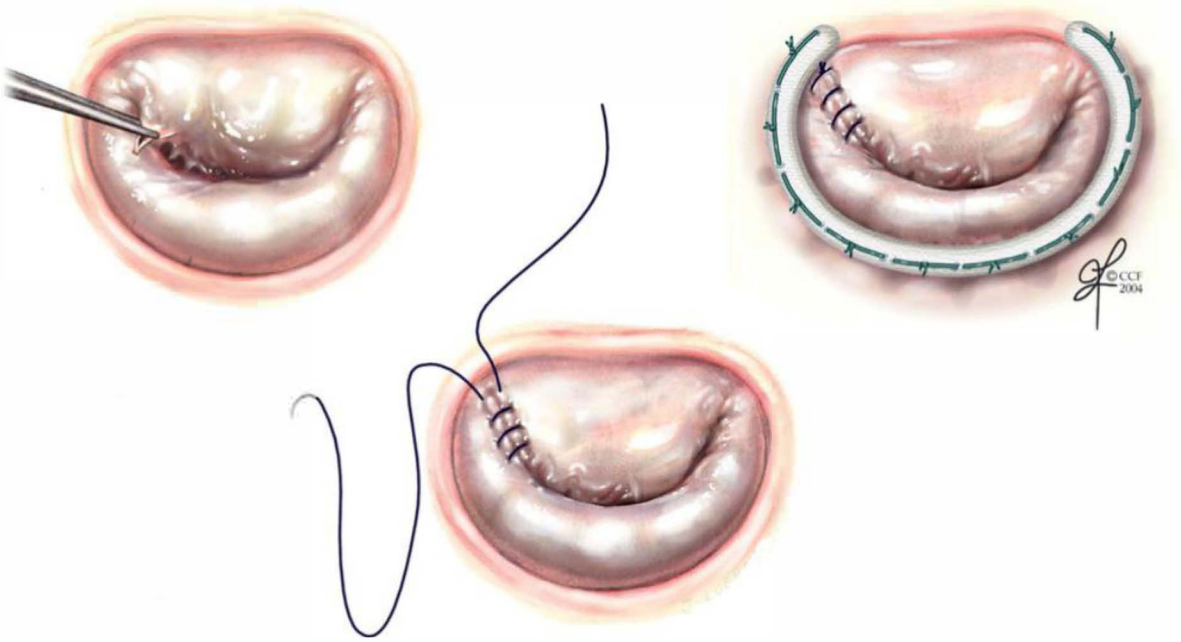

**FIGURE 36-6** Commissuroplasty. Commissure is closed with running suture. Annuloplasty completes the repair. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

In patients with symmetric bileaflet prolapse, a central jet of regurgitation, and no flail, repair can be achieved with a large annuloplasty device (36 mm or greater). This reduces annular diameter and increases leaflet coaptation. Although this is a simple technique, close attention must be paid to the height of the posterior leaflet to avoid postrepair SAM.

In patients with severe bileaflet prolapse, it is often necessary to address both leaflets, necessitating a combination of repair techniques (i.e., resection and sliding repair of the posterior leaflet, artificial chordae for the anterior leaflet, or chordae for both the anterior and posterior leaflet to suspend all valve segments, and annuloplasty to increase leaflet coaptation).

### Annuloplasty Devices

Annuloplasty is a component of all repairs for degenerative mitral valve disease. Use of a prosthetic annuloplasty improves repair durability.[13] Although there are many annuloplasty devices available—rigid vs flexible, complete vs partial—the truth is that all work well in patients with degenerative mitral valve disease. The surgeon should choose the annuloplasty device with which he or she is most comfortable.

## MITRAL VALVE REPAIR—SURGICAL APPROACHES

There are a variety of surgical approaches to repairing the mitral valve. The key decisions regarding choice of approach include safety and efficacy. Although a minimally invasive approach is desirable, it is only advisable if safety and effectiveness can be maintained.

### Complete Sternotomy

This is the standard approach for most cardiac operations. Central cannulation is achieved via the ascending aorta and the superior and inferior vena cavae. The heart is protected with both antegrade and retrograde cardioplegia. The mitral valve is exposed via a transverse left atriotomy anterior to the insertion of the right superior and inferior pulmonary veins.

### Right Mini-Thoracotomy

The right mini-thoracotomy approach is increasingly popular for treatment of patients with mitral valve dysfunction and can be employed in patients requiring concomitant management of atrial fibrillation or tricuspid regurgitation as well. Although minor variations abound, the most common approach includes a 4- to 8-cm skin incision in the inframammary crease lateral to the nipple and entry into the chest via the fourth intercostal space (Fig. 36-7). Patient preparation includes a double-lumen endotracheal tube and positioning with a roll placed under the right scapula; the right arm is distracted 5 to 10 cm to provide working room for the surgeon and to enable placement of a transthoracic aortic cross-clamp. After entry into the fourth intercostal space under single-lung isolation, a soft tissue retractor is placed to improve exposure and to protect the intercostal neurovascular bundle. A stainless steel rib retractor is positioned next. Occasionally the diaphragm obscures exposure of the pericardium near the inferior vena cava; a stay suture in the central tendon of the right hemidiaphragm, brought out through the fifth or sixth intercostal space, improves exposure. The pericardium is opened 3 cm or more anterior to the phrenic nerve, and stay sutures brought through the chest wall in the midaxillary line to retract the pericardial edge.

Cardiopulmonary bypass is established via peripheral cannulation. The anterior surfaces of the femoral artery and vein are exposed and cannulated with a modified Seldinger technique. Under transesophageal echocardiographic guidance, the tip of a long dual-stage venous cannula is advanced into the superior vena cava. The leading edge of the cannula should be advanced at least 4 cm into the superior vena cava to prevent migration back into the right atrium, which can lead to inadequate venous drainage and obscure exposure of the mitral valve. A femoral arterial cannula is also placed. Aortic occlusion is accomplished with a transthoracic cross-clamp inserted through the third intercostal space in the midaxillary line; alternative methods of aortic occlusion include a flexible clamp introduced into the field, or an endoaortic balloon introduced via the femoral arterial cannula and positioned with echocardiographic guidance.

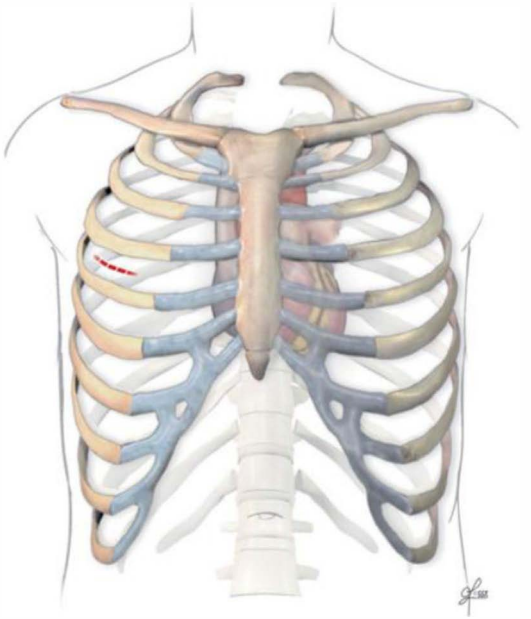

**FIGURE 36-7** Right mini-thoracotomy. A 6-to-8-cm incision in the fourth intercostal space, peripheral cannulation, antegrade and retrograde cardioplegia. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

We favor the transthoracic clamp when using the nonrobotic right mini-thoracotomy approach. Myocardial protection is achieved with antegrade cardioplegia (catheter placed directly in ascending aorta or endoaortic balloon) and is frequently supplemented by retrograde cardioplegia and systemic hypothermia. Some surgeons prefer to perform the operation under fibrillatory arreset and do not occlude the aorta or employ cardioplegia.

The mitral valve is approached via a standard transverse left atriotomy. A static retractor is placed through the third intercostal space lateral to the internal thoracic artery which lifts the interatrial septum and exposes the mitral valve. Long-shafted instruments are used to perform the repair. Placement of annuloplasty sutures before leaflet repair improves exposure, particularly in the region of P3. A knot-pusher is used to tie sutures as tying by hand is not possible with this approach.

Right thoracic approaches are contraindicated in patients with small femoral vessels (less than 7 mm), peripheral arterial disease, aortic regurgitation that is moderate or greater, and pectus excavatum. Preoperative testing should include a computed tomography (CT) scan to determine femoral vessel size and to rule out peripheral arterial disease.

## Robotically Assisted Right Thoracic Approach

Robotically assisted mitral valve repair entails a right thoracic approach. Mastery of standard, minimally invasive, nonrobotic right thoracotomy technique is mandatory before progressing to robotically assisted surgery. The robotic, port-based approach includes placing a working port in the fourth intercostal space anterior to the anterior axillary line and a camera port in the fourth intercostal space 2 to 3 fingerbreadths anterior to the working port. The left robotic arm is placed in the third interspace 3 to 5 cm anterior to the anterior axillary line, the right arm in the fifth or sixth interspace at the anterior axillary line, and the atrial retractor arm in the fourth or fifth interspace in the midclavicular line (Fig. 36-8).

Cardiopulmonary bypass is established after cannulation of the femoral artery and vein, and venous drainage is occasionally augmented by a superior vena caval cannula introduced via the right internal jugular vein. As with a standard thoracotomy approach, aortic occlusion is achieved with a transthoracic clamp or the endoaortic balloon; the endoaortic balloon is preferred in patients with normal ascending aorta caliber (less than 3.7 cm in diameter). Myocardial protection includes antegrade cardioplegia, retrograde cardioplegia (via a percutaneous coronary sinus catheter), and moderate systemic hypothermia (cooling to 30° C).

## Partial Sternotomy

Although there was great initial enthusiasm for the partial sternotomy approach to mitral valve repair, this has recently been supplanted by interest in right-sided incisions that do not involve division of the sternum. The mitral valve can be approached via a 6- to 8-cm midline skin incision followed by either an upper or lower partial sternotomy (Fig. 36-9). With both approaches, central arterial cannulation and direct aortic cross-clamping are employed, making this the minimally invasive approach of choice in patients with small femoral arteries or peripheral arterial disease. With an upper sternotomy, venous drainage is achieved via separate cannulation of the superior and inferior vena cavae, while femoral venous cannulation is used with a partial lower sternotomy. Antegrade cardioplegia is delivered via a catheter placed directly in the ascending aorta. Mitral valve exposure with a partial upper sternotomy is obtained through an extended transseptal incision. When a partial lower sternotomy is used, the mitral valve can be exposed via a standard left atriotomy or transseptal approach. With a partial sternotomy approach, standard instrumentation is used for the repair, and sutures are tied by hand.

## MITRAL VALVE REPAIR—RESULTS

Repair durability, as measured by freedom from reoperation and recurrence of MR, is excellent. Mitral valve repair for degenerative disease is associated with an operative risk of less than 1 percent. Excellent long-term survival rates have been reported, with 10-, 15-, and 20-year survival rates of 92, 76, and 48 percent, respectively. The best results are achieved with early operation, before the onset of symptoms or change in cardiac structure or function.[14,15] Standard techniques that

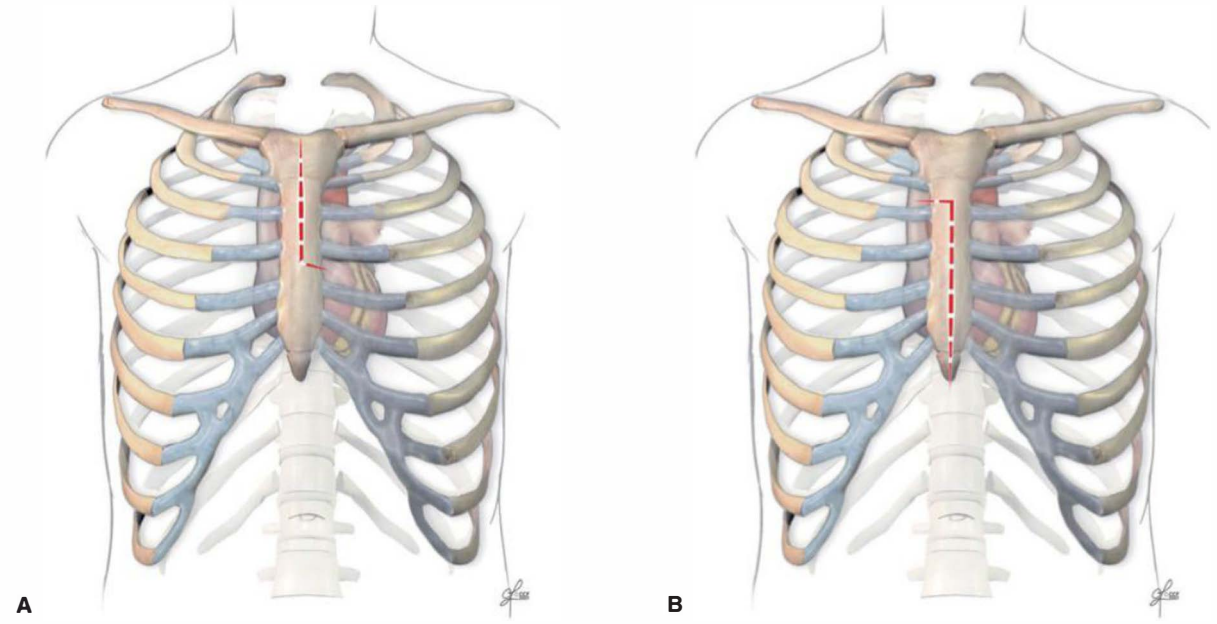

**FIGURE 36-9** **A.** Partial upper sternotomy. **B.** Partial lower sternotomy. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2004–2010. All Rights Reserved.)

include both leaflet repair and prosthetic annuloplasty are necessary to achieve these results. Some have reported less satisfactory outcomes, with higher hospital mortality and lower repair durability.[16] This emphasizes the importance of referring patients with degenerative disease to centers of excellence. Mitral valve repair accomplished with standard techniques is highly effective and reproducible.

## SUMMARY

The key to successful mitral valve repair is to apply appropriate repair techniques. Intraoperative transesophageal echocardiography will identify the site(s) of prolapse and assist with planning. The surgical approach (sternotomy vs a minimally invasive technique) should be determined based upon preoperative testing. When repairing the valve, it is wise to keep it simple; target the pathology identified by the echocardiogram and confirmed by direct inspection. Use standard, reproducible repair techniques. And always assess the result by echocardiography; do not leave the operating room with SAM or MR that is more than mild.

## MITRAL VALVE REPAIR FOR DEGENERATIVE DISEASE BOARD REVIEW QUESTIONS (CHAPTER 36)

1. The sliding repair technique for mitral repair was developed to:
   A. Avoid the creation of mitral stenosis with the repair
   B. Reduce the risk of postrepair systolic anterior motion
   C. Increase the area of the zone of leaflet coaptation
   D. Increase the long-term durability of the repair
   E. Obviate the need for placement of an annuloplasty band

2. An important advantage of the triangular resection technique over the quadrangular resection technique for mitral repair is:
   A. A higher success rate of repair
   B. More consistent anatomic landmarks for resection
   C. Reduction in the risk of incurring systolic anterior motion
   D. Obviates the need for annular plication sutures
   E. Can be performed for Barlow's pathology

3. One of the most important things to avoid in using artificial chordae for mitral repair is:
   A. Placing too many artificial chordae
   B. Spacing the artificial chordae too far apart
   C. Avoiding excessive tension at tying the artificial chordae
   D. Attaching the chordae too close to the free edge of the prolapsing leaflet
   E. Not using pledgets to affix the chordae to the papillary muscle tips

4. Which of the following is not a contraindication for performing a mitral repair through a right mini-thoracotomy?
   A. Patients with small femoral vessels (<7 mm)
   B. Moderate-to-severe aortic insufficiency
   C. Pectus excavatum
   D. Significant iliofemoral arterial atherosclerotic disease
   E. Obesity

5. The best clinical outcomes after mitral repair are achieved with:
   A. Early operation, before the onset of symptoms or significant change in cardiac structure or function
   B. Minimally invasive approaches
   C. Use of reduction annuloplasty alone
   D. Full sternotomy approach
   E. Using the largest annuloplasty band permissible

## ANSWERS

1. **Answer: B.** The sliding repair technique, or so-called "sliding-plasty," was developed to avoid excessive height of the posterior leaflet after resective repair. Excessive posterior leaflet height can protrude into the left ventricular outflow tract, creating a partial obstruction. This technique does not directly impact the mitral orifice area, the zone of coaptation, or durability of the repair. Placement of an annuloplasty band is recommended for virtually all types of mitral repair and is not obviated with the sliding repair technique.

2. **Answer: D.** One of the triangular resection technique's advantages over the quadrangular resection method in treating posterior leaflet prolapse is eliminating the need to place posterior annular plication sutures. Since the triangular resection does not leave a gap along the annulus, this annulus does not need to be plicated as with a posterior quadrangular resection. The triangular resection technique is not associated with a higher success rate for repair, nor does it reduce the risk for incurring systolic anterior motion. The anatomic landmarks for resection are similar to that for quadrangular resection. Both the quadrangular and triangular techniques can be used for Barlow's pathology.

3. **Answer: C.** An important technical pitfall to avoid in the use of artificial chordae is to avoid tying the chordae too tightly, leading to chordae that are too short and a restricted leaflet. The number and spacing of the chordae are not critical considerations, so long as they are of the proper length. The chordae should be placed at the free edge of the leaflet. The use of pledgets to reinforce the chordae attachment to the papillary muscle tips is variable.

4. **Answer: E.** Contraindications for performing a mitral repair through a right mini-thoracotomy include small femoral vessel caliber and significant iliofemoral artery disease, since femoral arterial cannulation is required with this approach. Moderate-to-severe aortic insufficiency is also a contraindication since antegrade cardioplegia is the primary mode of arrest with this technique. Significant pectus excavatum presents significant difficulty in obtaining adequate exposure with this intercostal approach. Although obesity can present challenges with exposure, it is not a strong contraindication for this approach.

5. **Answer: A.** The best clinical outcomes after mitral repair are associated with early operation, before the onset of symptoms or significant change in cardiac structure or function. Although minimally invasive approaches appear to confer advantages in early postoperative recovery, long-term outcome advantages have not been established conclusively with either less-invasive or full sternotomy approaches. The use of reduction annuloplasty alone is generally not adequate for posterior or anterior leaflet prolapse. Using the largest annuloplasty band permissible in all types of repairs is not advised; using the most appropriately sized band to address the pathology is recommended.

# Tricuspid Valve Disease

*David L. Joyce*

## KEY CONCEPTS

- Epidemiology
  - Although as many as 70 percent of Americans may have a small amount of tricuspid regurgitation (TR) on echocardiogram, true disease of the tricuspid valve only affects 0.8 percent of the population. Approximately 8000 surgical procedures are performed for tricuspid disease each year in the United States. The most common manifestation of tricuspid valve disease is functional TR, which occurs secondary to left-sided heart valve disease and is present in approximately 30 percent of patients with severe mitral regurgitation and up to 53 percent of patients undergoing mitral valve surgery. Risk factors for TR include age (OR 1.5/9.9 years; 95 percent CI 1.3–1.7), body mass index (OR 0.7/4.3 kg/m$^2$; 95 percent CI 0.6–0.8), and female gender (OR 1.2; 95 percent CI 1.0–1.6).
- Pathophysiology
  - In most cases, tricuspid valve disease presents as functional regurgitation secondary to left-sided valvular disease or heart failure (particularly in the setting of pulmonary hypertension). Structural causes of tricuspid valve disease are less common, and include rheumatic heart disease, endocarditis, carcinoid, papillary muscle dysfunction, trauma (often from endomyocardial biopsies or pacemaker lead placement), and congenital anomalies.
- Clinical features
  - Tricuspid valve disease is often detected incidentally during evaluation for left heart conditions. Signs and symptoms are often consistent with congestive heart failure and can include dyspnea on exertion, orthopnea, jugular venous distention, ascites, and peripheral edema. Advanced disease also can present with hemoptysis and paroxysmal nocturnal dyspnea. Physical examination reveals a pansystolic (TR) or presystolic [tricuspid stenosis (TS)] murmur in the fourth and fifth intercostal spaces at the left sternal border or epigastrium. Hepatojugular reflux, pulsatile liver, and signs of hepatic dysfunction also may be present. Tricuspid endocarditis often presents with pneumonia or manifestations of septic emboli.
- Diagnostics
  - Electrocardiographic features include peaked P waves or a Q wave in V1 as a result of right atrial volume overload and enlargement. Plain chest radiography may demonstrate cardiomegaly with right-sided chamber enlargement. Doppler and two-dimensional echocardiography confirm the diagnosis, revealing structural abnormalities and measuring pulmonary arterial pressures, degree of stenosis/regurgitation, and right ventricular dysfunction. Cardiac catheterization usually confirms elevated right atrial and ventricular end-diastolic pressures in TR. A diastolic pressure–atrioventricular pressure gradient that increases with respiration is found in patients with significant TS. Tricuspid endocarditis is typically diagnosed in the setting of major criteria that include valvular vegetations and pyrexia; positive blood cultures, septic pulmonary emboli, and a murmur constitute the minor criteria.
- Treatment
  - Tricuspid valve repair or replacement is indicated for TS and moderate-to-severe TR, usually associated with New York Heart Association class III or IV symptoms. TS is usually treated with commissurotomy.
  - Surgical techniques for TR include bicuspidization, DeVega suture annuloplasty, Carpentier ring annuloplasty, and prosthetic valve replacement.
- Outcomes
  - Untreated, the 1-year survival in patients with severe, moderate, mild, and absent TR is approximately 60, 70, 90, and 91 percent, respectively. The DeVega suture annuloplasty for TR is associated with a 4 percent operative mortality, a 5 percent recurrence rate, and an actuarial survival rate of 71.5 percent at 14 years. Carpentier ring annuloplasty is associated with an actuarial survival of 68.3 percent at 10 years.

# INTRODUCTION

## Definitions

Diseases of the tricuspid valve can be subdivided in several ways. The broadest distinction separates congenital lesions (e.g., Ebstein's anomaly, tricuspid atresia) from those which are acquired. This chapter focuses primarily on acquired lesions, which can be divided into functional (secondary) disease and organic (primary) disease. Functional disease typically occurs in the setting of an anatomically normal valve and results from pulmonary artery hypertension and right ventricular (RV) dilatation. This condition most often is secondary to left-sided valvular disease but also may result from Eisenmenger's syndrome, RV infarction, or primary pulmonary hypertension (PPH). These types of disease typically manifest in the clinical presentation of tricuspid regurgitation (TR). Organic disease (in which there is a structural abnormality of the valve) is associated most frequently with rheumatic fever but also may occur in the setting of congenital anomalies, infective endocarditis, radiation therapy, trauma (from endomyocardial biopsies or pacemaker lead insertion), carcinoid syndrome, Libman–Sacks endocarditis, eosinophilic leukemia, and diffuse collagen disorders. Tricuspid stenosis (TS) is often present in organic disease, although insufficiency can occur alone or in combination with stenosis. A summary of the disorders implicated in tricuspid valve regurgitation is given in Figure 37-1.

## Historic Highlights

Starr and colleagues[1] reported the first surgical experience with tricuspid valve replacement (TVR) in a series of 13 patients who had undergone multiple valve replacement; one of those patients underwent replacement of the aortic, mitral, and tricuspid valves on February 21, 1963. Although the paucity of indications for TVR limited its implementation, the recognition of tricuspid valve endocarditis as an epidemic among heroin addicts in Detroit between 1966 and 1968 rejuvenated interest in tricuspid valve surgery. Valve

replacement combined with intravenous antibiotics failed to control severe gram-negative sepsis, yielding a mortality rate of 100 percent. In search of a more efficacious treatment strategy, Agustin Arbulu began performing experimental removal of the tricuspid valve. After demonstrating the efficacy of this technique in a canine model, Arbulu removed the tricuspid valve in 55 patients with tricuspid endocarditis secondary to *Pseudomonas aeruginosa* with a 61 percent survival rate at 25 years.[2,3]

## Anatomic Considerations

The tricuspid valve complex contains the following structures (Fig. 37-2)[4]:

- Three leaflets (anterior, posterior, and septal)
- The chordate tendinae
- Two papillary muscles
  - The anterior papillary muscle gives chordae to the anterior and posterior leaflets.
  - The medial papillary muscle gives chordae to the posterior and septal leaflets.
- The fibrous tricuspid annulus
- The right atrial and RV myocardium.

The adult valve is typically 36 ± 4.5 mm in diameter and covers a surface area of 10.5 $cm^2$. In the setting of dilated cardiomyopathy, the valve diameter can increase to 45 mm in some cases. Important anatomic considerations for the surgeon include the presence of the atrioventricular node (AVN) and conducting system within the triangle of Koch demarcated as the base of the septal leaflet, coronary sinus orifice, and tendon of Todaro. The relationships of the annulus to the base of the aortic valve, the membranous septum, the central fibrous body, the right coronary artery, and the lateral atrioventricular junction are also important.

# PATHOPHYSIOLOGY

Disorders of the tricuspid valve can result from structural abnormalities or changes in ventricular geometry in the setting of a normal valve. TS is due to rheumatic heart disease in over 90 percent of cases.[4] Conversely, pure TR is usually a consequence of RV dilatation and failure.

## Tricuspid Stenosis

The surgical pathology of TS can be divided into four categories: rheumatic disease, congenital anomalies, metabolic

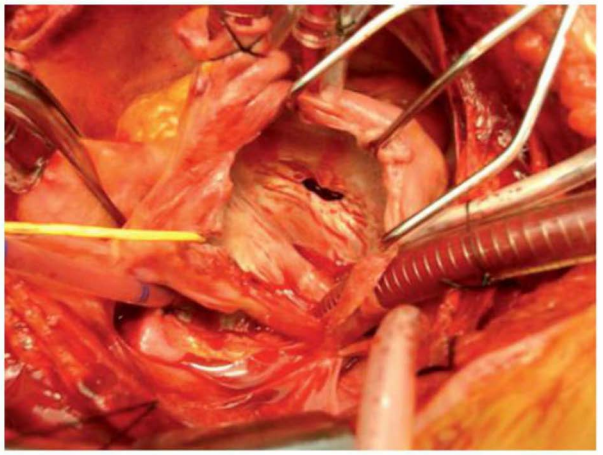

FIGURE 37-3 Surgical finding of a stenotic tricuspid valve secondary to rheumatic heart disease. (Image reprinted with permission from Medscape Reference (http://emedicine.medscape.com/), 2013, available at http://emedicine.medscapte.com/article/158604-overview.)

disorders, and infective endocarditis.[5] On gross pathology, stenotic tricuspid valves are found to have fibrous thickening of the leaflets with shortening and thickening of the chordae tendineae. Fusion of the commissures leads to obstruction of blood flow and the resultant symptoms of TS (Fig. 37-3). Histologic examination of the valvular tissue reveals deposition of collagen and elastic fibers.[5]

## Tricuspid Regurgitation

Regurgitation of the tricuspid valve results from a wide array of entities. Worldwide, the most common causes of TR include rheumatic heart disease and endocarditis.[6] Other less common causes of organic TR include carcinoid, papillary muscle dysfunction, trauma, connective tissue disorders, rheumatoid arthritis, and radiation therapy.[7] In North America, functional TR is more prevalent secondary to annular dilatation and the sequelae of left-sided valvular disease and pulmonary hypertension.[6] Gross pathologic features of the regurgitant tricuspid valve include fibrous thickening of the leaflets, minimal calcification, and dilatation of the annulus.[7] In contrast to TS, there is no fusion of the commissures or shortening of the chordae.

# CLINICAL FEATURES

## Epidemiology

Tricuspid valve disease affects 0.8 percent of Americans, making it a much rarer condition than diseases of the mitral valve, which affect 2.4 percent and 1.6 percent of the general population.[8] Although most patients with tricuspid disease are treated medically, approximately 8000 surgical procedures are performed for tricuspid disease each year in the United States.[8] The most common manifestation of tricuspid valve disease is functional TR, which occurs secondary to left-sided heart valve disease and is present in approximately 30 percent of patients with severe mitral regurgitation and up to 53 percent of patients undergoing mitral valve surgery.[8] Internationally, tricuspid valve disease is more common due to the increased prevalence of rheumatic heart disease. In Latin America and India, this condition affects 4 out of every 100,000 people. In the Framingham Heart Study, the determinants of TR were age (OR 1.5/9.9 years; 95 percent CI 1.3–1.7), body mass index (OR 0.7/4.3 kg/m$^2$; 95 percent CI 0.6–0.8), and female gender (OR 1.2; 95 percent CI 1.0–1.6).[9]

## History and Physical Examination

Signs and symptoms of tricuspid valve disease are illustrated in Table 37-1.[10] Tricuspid valve disease usually is brought to the attention of the medical practitioner during evaluation of left-sided conditions. A history of rheumatic heart disease or an abnormality detected on cardiac auscultation may alert the clinician, but frequently these patients present with dyspnea on exertion, orthopnea, and other symptoms of left-sided failure. In advanced cases, hemoptysis and paroxysmal nocturnal dyspnea may occur.[11]

Signs of tricuspid valve disease are related to the onset of right heart failure and include jugular venous distention, ascites, and peripheral edema. Patients also may complain of vague abdominal discomfort associated with hepatomegaly. In light of the high rate of concordant left-sided disease, most patients are detected on the basis of congestive heart failure. Physical examination is notable for the presence of a murmur, which can be auscultated

at the left sternal edge at the fourth and fifth intercostal spaces or in the epigastrium. The murmur of TR is pansystolic and may be high-pitched, often increasing on inspiration (Carvallo's sign). TS produces a presystolic murmur that also increases with inspiration. This feature permits its differentiation from murmurs associated with mitral valve disease. An S3 may be appreciated in cases of ventricular dilatation, while an S4 may indicate a hypertrophied ventricle. Atrial fibrillation is a common finding. Hepatojugular reflux or a pulsatile liver may be demonstrated in cases of TR, and clinical signs of hepatic dysfunction also may be present.

## DIAGNOSTIC MODALITIES

In 2006, the American College of Cardiology (ACC) and American Heart Association (AHA) introduced guidelines for the evaluation of TR in adolescents and young adults.[12] These recommendations are summarized in Table 37-2. Routine laboratory tests may aid in the diagnosis of the underlying condition, with leukocytosis commonly seen in the setting of infective endocarditis. Renal and hepatic impairment also may be present in cases of chronic ventricular dysfunction.

**TABLE 37-2: ACC/AHA Guidelines for Evaluation of Tricuspid Regurgitation (TR) in Adolescents and Young Adults**

**Class I—There is evidence and/or general agreement that the following tests should be obtained in adolescents and young adults with TR**

Electrocardiogram at the initial evaluation and serially every 1 to 3 years, depending upon severity

Chest radiograph at the initial evaluation and serially every 1 to 3 years, depending upon severity

Doppler echocardiography at the initial evaluation and serially every 1 to 3 years, depending upon severity

If an atrial communication is present, pulse oximetry at rest and/or during exercise at the initial evaluation and serially every 1 to 3 years, depending upon severity

**Class IIa—The weight of evidence or opinion is in favor of the usefulness of the following tests in adolescents and young adults with TR**

Electrophysiology study for symptomatic atrial arrhythmias

Exercise testing at the initial evaluation and serially every 1 to 3 years

**Class IIb—The weight of evidence or opinion is less well established for the usefulness of the following tests in adolescents and young adults with TR**

Among asymptomatic patients, Holter monitoring at the initial evaluation and serially every 1 to 3 years

Reproduced with permission from Bonow RO, Carabello BA, Chatterjee K, et al. ACC/AHA 2006 guidelines for the management of patients with valvular heart disease. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *J Am Coll Cardiol* 2006;48:e1.

Electrocardiographic findings include peaked P waves (caused by right atrial overload) or a Q wave in $V_1$ (resulting from an enlarged right atrium). Posteroanterior and lateral plain chest radiography may demonstrate cardiomegaly with enlargement of the right-sided cardiac structures. A pleural effusion also may be present along with upward displacement of the diaphragm resulting from ascites. Echocardiography represents the mainstay of diagnostic evaluation, with color flow mapping used in two orthogonal planes to estimate severity by analysis of vena contracta width, flow convergence calculations, and evaluating the direction and size of the jet.[4] Specific echocardiographic criteria for severe TR include vena contracta width greater than 0.7 cm, Proximal Isovelocity Surface Area (PISA) radius greater than 0.9 cm (at Nyquist limit of 50–60 cm/s), systolic flow reversal in the hepatic veins, and dilatation of the RV, right atrium, and inferior vena cava.[8] Structural abnormalities of the valve can be demonstrated along with measurement of pulmonary artery pressures and RV function. Interpretation of echocardiographic findings of TR must be taken in the context of the patient's clinical condition, since severity can be influenced by dynamic properties such as volume status and afterload.[4]

Right heart catheterization provides useful information for evaluating the anatomy and functionality of the tricuspid valve. In the setting of TR, right atrial and ventricular end-diastolic pressures usually are elevated. TS is characterized by a diastolic pressure gradient between the right atrium and the right ventricle that increases during inspiration and decreases with expiration. Contrast right ventriculography is rarely needed in the workup of tricuspid valve disease due to the abundance of useful information that can be gained from transthoracic echocardiography. In older patients and those with risk factors for coronary artery disease, a left heart catheterization may be required to document the status of the coronary circulation.

## MEDICAL THERAPY

Acquired disease of the tricuspid valve represents a structural abnormality for which there is no effective pharmacotherapy. In general, tricuspid insufficiency is well tolerated in the absence of elevated pulmonary pressures. For example, echocardiograms performed in 95 healthy women revealed some degree of TR in 52 subjects.[13] Medical therapy is directed toward addressing the underlying cause of pulmonary hypertension, such as treating chronic obstructive pulmonary disease (COPD). Diuretics may be effective in reducing peripheral edema and hepatic congestion. Nevertheless, elevation of the pulmonary vascular resistance may dictate surgical repair in selected patients. TS has been treated with balloon valvotomy in several small series. However, there are no published studies that compare balloon valvotomy with surgical valvuloplasty. In addition, severe TR is a common complication of balloon valvotomy.

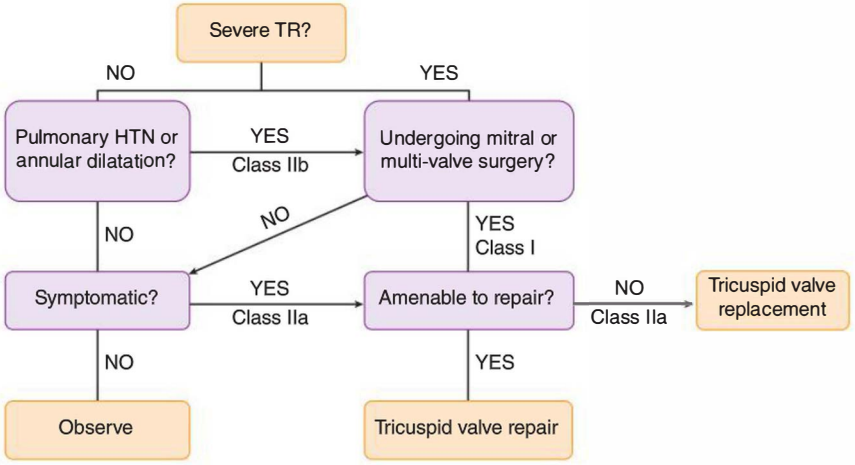

**FIGURE 37-4** Flow diagram for the management of tricuspid regurgitation.

# SURGICAL THERAPY

## Surgical Decision Making

A flow diagram for surgical decision making is provided in Figure 37-4. In addition, ACC/AHA guidelines are reviewed in Table 37-3. Tricuspid valve repair is indicated in patients with severe TR who are undergoing mitral valve surgery or multiple valve surgery.[12] It is reasonable to consider tricuspid valve repair or replacement in cases of severe symptomatic primary TR as well as in mild TR in patients undergoing mitral valve surgery in the setting of pulmonary hypertension or tricuspid annular dilatation.[12] Tricuspid valve surgery should not be considered in patients with mild primary TR or those who are asymptomatic with a normal mitral valve and pulmonary artery systolic pressures of less than 60 mm Hg.[12]

## Operative Techniques

Surgical management of acquired diseases of the tricuspid valve has evolved from reparative techniques to prosthetic replacement and back again after greater experience with and modifications of each of those techniques. Since operative repair of tricuspid valve lesions is performed most commonly in the setting of concomitant cardiac surgical procedures, median sternotomy is typically the approach of choice.

### TRICUSPID STENOSIS: COMMISSUROTOMY

For TS that is not amenable to balloon valvuloplasty, surgical management is straightforward and involves commissurotomy of the diseased valve. Successful commissurotomy requires adequate visualization of the valve and careful attention to the surrounding anatomic structures.[14] It is usually unnecessary to open all three commissures, since such maneuvers are likely to result in significant tricuspid insufficiency that is difficult to correct. Instead, separation of the fused commissures on either side of the septal leaflet results in a

**TABLE 37-3: ACC/AHA Guidelines for Surgical Management of Tricuspid Valve Disease**

**Class I**

Tricuspid valve repair is beneficial for severe TR in patients with MV disease requiring MV surgery
(Level of Evidence: B)

**Class IIa**

1. Tricuspid valve replacement or annuloplasty is reasonable for severe primary TR when symptomatic
(Level of Evidence: C)
2. Tricuspid valve replacement is reasonable for severe TR secondary to diseased/abnormal tricuspid valve leaflets not amenable to annuloplasty or repair
(Level of Evidence: C)

**Class IIb**

Tricuspid annuloplasty may be considered for less than severe TR in patients undergoing MV surgery when there is pulmonary hypertension or tricuspid annular dilatation
(Level of Evidence: C)

**Class III**

1. Tricuspid valve replacement or annuloplasty is not indicated in asymptomatic patients with TR whose pulmonary artery systolic pressure is less than 60 mm Hg in the presence of a normal MV
(Level of Evidence: C)
2. Tricuspid valve replacement or annuloplasty is not indicated in patients with mild primary TR
(Level of Evidence: C)

straight (septal) and a curved (mural) leaflet with excellent hemodynamic properties.[15]

## TRICUSPID REGURGITATION

Surgical techniques for addressing TR include bicuspidization, purse-string (DeVega) reduction of the annulus, placement of rigid or flexible annuloplasty (Carpentier) rings, and prosthetic replacement. Selection of the appropriate treatment depends on the extent of dysfunction and the condition of the native valve. The goals of therapy include restoration of normal valve function through the use of an easily reproducible technique that yields consistent results.[16]

***Bicuspidization.*** The posterior annulus of the tricuspid valve is the only structurally unsupported area of the tricuspid valve annulus, making this area particularly susceptible to dilatation and subsequent TR.[16] Various annuloplasty techniques have been described that are based on the principle of correcting this abnormality.[6] Bicuspidization for tricuspid insufficiency is performed using one or two pledgeted polypropylene sutures to obliterate the annular segment corresponding to the posterior leaflet. This technique is generally satisfactory in patients with moderate TR. In a similar technique, an edge-to-edge repair can be used to reduce the size of the regurgitant annulus.

***DeVega Suture Annuloplasty.*** Owing to its simplicity, the DeVega repair has gained popularity for the management of moderate-to-severe TR. This technique involves running a single pledgeted polypropylene suture between the anterior and septal leaflets at the level of the commissure.[6] Two sequential sutures are placed in this fashion, running clockwise through the annulus. These sutures are tightened to obliterate the portion of the annulus that has been plicated (Fig. 37-5). On the basis of some estimates, up to 26 percent of patients undergoing surgery of the mitral or aortic valve may require tricuspid annuloplasty.[17] Operative mortality after DeVega annuloplasty is around 4 percent.[18] Recurrence of tricuspid insufficiency has been demonstrated in 5 percent of patients undergoing this procedure and has been attributed to an inadequate mitral valve procedure or left ventricular failure.[19] Long-term follow-up of this procedure shows an actuarial survival rate of 71.5 ± 8.2 percent at 14 years.[20]

***Carpentier Ring Annuloplasty.*** In cases of severe TR, rigid or flexible ring annuloplasty is well accepted as optimal therapy. The principles of repair are similar to those for suture annuloplasty with respect to reducing the size of the valve orifice. However, the increase in dilatation seen in cases of severe TR mandates greater stability with the repair. A sizer is used to measure the area of the septal leaflet to allow selection of the appropriate ring. Tricuspid rings are designed with an opening that corresponds to the region of the AVN to minimize the chance of incurring damage to the conducting system during surgery. Interrupted pledgeted 2-0 non-absorbable sutures are placed through the annulus and then passed through the ring, securing it in place (Fig. 37-6). First described by Carpentier and colleagues,[21] this procedure has undergone several modifications. Nevertheless, the principles of repair remain the same regardless of the type of ring used. This technique has been estimated to be suitable in up to 96 percent of cases of acquired tricuspid valve disease and is associated with a hospital mortality rate of 9 to 10 percent in patients undergoing concomitant left-sided valve surgery (nonvalve-related deaths).[22] Actuarial survival from this procedure at 10 years is 68.3 percent.[23] A recent study comparing several different suture and ring annuloplasty techniques demonstrated an increase in recurrent TR over time with the DeVega annuloplasty.[24] These findings have led to the recommendation that suture annuloplasties be abandoned in favor of various types of ring annuloplasties to reduce the rate of reoperation, which has an associated hospital mortality rate of 37 percent.[24]

## TRICUSPID VALVE REPLACEMENT

After tricuspid valve repair, assessment of persistent insufficiency can be determined by one or more of the following techniques: (1) injection of saline into the right ventricle with a clamp occluding the pulmonary artery; (2) manual palpation

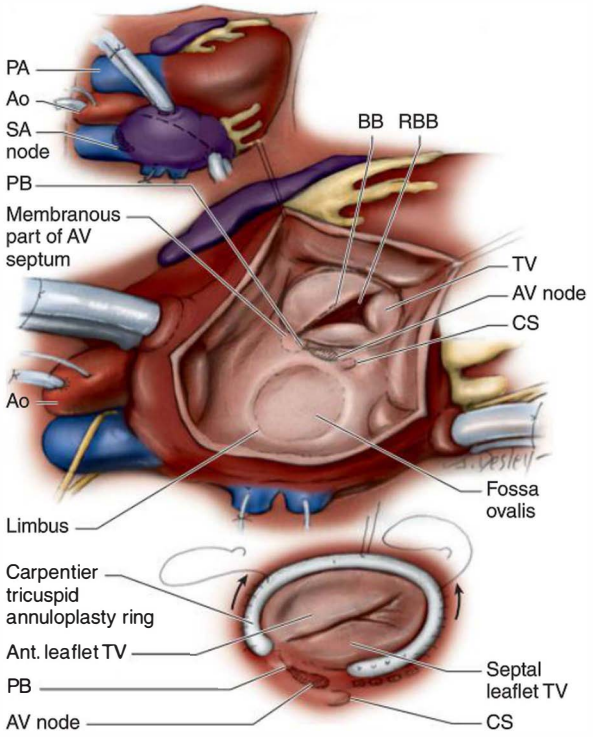

**FIGURE 37-6** Technique for tricuspid annuloplasty using a Carpentier–Edwards ring. for regurgitant flow performed by inserting a finger through the right atrial appendage; and (3) transesophageal echocardiography. Valve replacement should be performed in cases of persistent tricuspid insufficiency or in instances where the valve morphology is not suitable for repair at the time of initial inspection. Predictors for the need for valve replacement include jugular venous distention, increased severity of tricuspid valve incompetence, previous cardiac surgery, and the presence of TS.[25] Because of the increased rate of thromboembolism and valve thrombosis associated with mechanical valve replacement, tissue valves are preferred in most cases. In a meta-analysis of 1160 prosthetic valves, the pooled survival hazard ratio of mechanical prosthesis versus bioprosthesis was found to be 1.07.[26] The freedom from reoperation hazard ratio was 1.24 in that study.[26] Survival rates have been found to be similar between the two types of valve replacement. The surgical technique involves placement of interrupted pledgeted non-absorbable imbricating sutures that are passed initially through the leading edge of the valve leaflets and subsequently through the prosthetic valve sewing ring (Fig. 37-7). Paying careful attention to the regional anatomy and leaving the native valve leaflets in place reduce the likelihood of injury to the conduction system.

## OUTCOMES/PROGNOSIS

Based on the results of a large retrospective VA study, severe TR has been found to be associated with a poor prognosis; this risk exists independent of age, biventricular systolic function, RV size, and dilation of the inferior vena cava.[27] Increase in the severity of TR has also been demonstrated to correlate with worsening survival, with 1-year survival rates of 90.7 percent with no TR, 90.3 percent with mild TR, 78.9 percent with moderate TR, and 63.9 percent with severe TR.[27] Improvement in outcomes has been consistently demonstrated with surgical correction of severe TR. In a recent study by Kim et al., operative mortality was 10 percent for isolated severe TR.[28] Factors that were associated with a poorer prognosis included preoperative anemia and

larger RV end systolic area.[28] When tricuspid valve replacement or repair is undertaken after left-sided valve surgery, the outcomes are improved with no hospital mortality and 1-, 5-, and 10-year survival of 97, 93, and 63 percent after replacement and 93, 93, and 81 percent after repair in a recent study by Park et al.[29] In this study, LV ejection fraction <40 percent and age were both found to be independent risk factors for mortality.[29] Although tricuspid valve repair remains the procedure of choice in cases of severe TR, valve replacement represents an acceptable alternative when repair is not possible.

## TRICUSPID VALVE DISEASE BOARD REVIEW QUESTIONS (CHAPTER 37)

1. Which structure is not associated with the triangle of Koch?
   A. Atrioventricular node
   B. Coronary sinus
   C. Septal leaflet
   D. Tendon of Todaro
   E. Right coronary artery

2. Which of the following represents one of the major Doppler criteria for severe TR?
   A. Vena contracta width >0.7 cm
   B. Annular dilation
   C. Paradoxical interventricular septal movement
   D. Hyperdynamic RV function
   E. Pulmonary hypertension

3. Which of the following is not an indication for tricuspid valve surgery?
   A. Severe TR in patients with mitral valve disease requiring mitral valve surgery
   B. Severe symptomatic primary TR
   C. Severe TR secondary to diseased/abnormal tricuspid valve leaflets
   D. Severe TR in patients undergoing mitral valve surgery when there is pulmonary hypertension or tricuspid annular dilation
   E. TR and pulmonary artery systolic pressure is less than 60 mm Hg

4. A patient requires mitral and tricuspid valve repair along with coronary artery bypass grafting to the PDA. What is the proper sequence for this operation?
   A. Mitral valve repair, tricuspid valve repair, distal coronary anastomosis, proximal anastomosis
   B. Distal coronary anastomosis, mitral valve repair, proximal anastomosis, tricuspid valve repair
   C. Distal coronary anastomosis, mitral valve repair, tricuspid valve repair, proximal anastomosis
   D. Tricuspid valve repair, mitral valve repair, distal coronary anastomosis, proximal anastomosis
   E. Mitral valve repair, distal coronary anastomosis, tricuspid valve repair, proximal anastomosis

5. Which of the following statements is true regarding surgical approach to the tricuspid valve?
   A. Jugular venous distention, increased severity of tricuspid valve incompetence, previous cardiac surgery, and the presence of TS all mandate valve replacement
   B. Mechanical valve replacement is preferred over tissue valve replacement given the high rate of complications with bioprosthetic valves
   C. Persistent leak after bicuspidization warrants valve replacement
   D. The DeVega technique is acceptable for cases of functional TR in which the loading conditions are expected to improve over time
   E. Ring annuloplasty techniques have a higher rate of endocarditis compared with alternative repair techniques

## ANSWERS

1. **Answer: E.** The right coronary artery is not associated with the triangle of Koch. The triangle of Koch is formed by the septal leaflet of the tricuspid valve, the coronary sinus, and the tendon of Todaro. The AVN is contained within this triangle.
2. **Answer: A.** Although all of these findings may be present in severe TR, major Doppler criteria include vena contracta width >0.7 cm and systolic flow reversal in the hepatic veins. Atrial fibrillation may limit the accuracy of systolic flow reversal as a finding.
3. **Answer: E.** Tricuspid valve repair is indicated in patients with severe TR who are undergoing mitral valve surgery or multiple valve surgery. It is reasonable to consider tricuspid valve repair or replacement in cases of severe symptomatic primary TR as well as in mild TR in patients undergoing mitral valve surgery in the setting of pulmonary hypertension or tricuspid annular dilatation. Tricuspid valve surgery should not be considered in patients with mild primary TR or those who are asymptomatic with a normal mitral valve and pulmonary artery systolic pressures of less than 60 mm Hg.
4. **Answer: B.** Sewing the distal anastomosis first will prevent the dreaded complication of atrioventricular separation which can occur when lifting the heart after mitral valve procedures. It also permits cardioplegia to be given through the graft during subsequent repair procedures. Tricuspid annuloplasty can be performed after removal of the cross-clamp after the heart is beating.
5. **Answer: D.** Jugular venous distention, increased severity of tricuspid valve incompetence, previous cardiac surgery, and the presence of TS all represent risk factors for failed repair. However, their presence alone does not mandate valve replacement. Bioprosthetic valves do not carry a higher complication rate and are preferred in most cases of valve replacement. Persistent regurgitation may improve after ring annuloplasty in attempted bicuspidization procedures. The DeVega technique is an appropriate option for cases of functional TR in which the loading conditions are expected to improve over time. There is no evidence that endocarditis risk increases with ring annuloplasty.

# Surgical Treatment of Endocarditis

*John R. Doty*
*William T. Caine*

## KEY CONCEPTS

- Epidemiology
  - The overall incidence of infective endocarditis in the general population ranges from 3 to 11 cases per 100,000 person-years. The most common underlying conditions are native valvular heart disease, previously implanted prosthetic valves and congenital heart disease. Endocarditis is more common in the elderly and males. The increasing use of indwelling intravenous catheters and leads for cardiac rhythm devices is associated with iatrogenic endocarditis.
- Pathophysiology
  - There are five distinct steps in the sequence of events resulting in endocarditis. First, there is damage to the endocardial surface of the valve or other cardiac structure. Second, there is the accumulation of thrombus and platelets on the damaged surface, termed nonbacterial thrombotic endocarditis (NBTE). Third, the patient develops a transient blood stream infection, usually bacteremia. Fourth, there is deposition and adherence of infectious organisms on the focus of NBTE. Fifth, the organisms grow and multiply at the NBTE site.
- Clinical Features
  - The clinical presentation of endocarditis depends upon the rapidity of onset, the virulence of the underlying organism, and the coexistence of underlying cardiac disease. Patients with acute endocarditis usually present early in the infection with substantial illness. Complications are common and are due to embolism and valvular destruction. Such complications include brain embolism, intracranial hemorrhage, heart failure, myocardial infarction, and peripheral embolism.
- Diagnostics
  - Physical examination, blood cultures and echocardiography are the cornerstones for the diagnosis of endocarditis. Adherence to the major and minor criteria of the modified Duke classification guide diagnosis and subsequent management. Transthoracic echocardiography is usually sufficient to identify the vegetation, but transesophageal provides the optimal method for establishment of endocarditis according to the Duke major criteria.
- Treatment
  - Prompt and accurate antimicrobial therapy should be initiated for the patient with endocarditis. In general, antibiotic therapy will be administered intravenously in high dosages for a prolonged period of time. The primary goals of operation for endocarditis are removal of all infected tissue and correction of the hemodynamic abnormality. Infection of a cardiac valve necessitates either repair or replacement.
- Outcome
  - Mortality after operation for endocarditis ranges widely, with reports of hospital death between 4 and 30 percent. In general, operative mortality is affected by the urgency of the operation, concomitant preoperative heart failure, nonstreptococcal organisms, and prosthetic valve endocarditis. Neurologic deficits can be worsened if surgery is performed within the first few weeks after the initial event. Recurrent endocarditis is uncommon (2–5 percent) if all infected tissue has been removed and there is no active infection at the time of operation.

## INTRODUCTION

Infective endocarditis (IE) is defined as any condition in which an infective process has affected a structure of the heart. The valves are the most common location for endocarditis, but the process may also involve atrial or ventricular septal defects, patent ductus arteriosus, or any of a wide range of congenital heart defects, including the aorta and great vessels. Depending on the involved area, the infective process can lead to progressive valvular dysfunction, systemic embolization, congestive heart failure, fistula formation, conduction abnormalities, and other organ dysfunction.

The presentation of IE includes acute, subacute, and chronic forms. In addition, the process can involve either the native structures of the heart or previously placed prostheses, such as valves or shunts. Organisms that cause endocarditis include bacteria, viruses, and fungi. Demonstration of both the organism and the sequelae of infection on cardiovascular function is essential for proper treatment.

The knowledge of established treatment guidelines for IE as well as the long-term sequelae of medically managed endocarditis is important for correct surgical therapy. Osler described the classical findings of endocarditis in 1885, and later stressed the importance of blood cultures for diagnosis.[1,2] Kay and colleagues were the first to describe successful surgical treatment of endocarditis in 1961, performing debridement of an infected tricuspid valve and simultaneous closure of a ventricular septal defect.[3] Wallace and colleagues performed the first valve replacement for aortic valve endocarditis in 1965.[4]

## PATHOGENESIS

There are five distinct steps in the sequence of events resulting in endocarditis. First, there is damage to the endocardial surface of the valve or other cardiac structure. Second, there is the accumulation of thrombus and platelets on the damaged surface, termed nonbacterial thrombotic endocarditis (NBTE). Third, the patient develops a transient blood stream infection, usually bacteremia. Fourth, there is deposition and adherence of infectious organisms on the focus of NBTE. Fifth, the organisms grow and multiply at the NBTE site.

### Damage to the Endocardial Surface

The endocardial surface may become damaged from one of several methods. Congenitally malformed valves or anomalous flow pathways, such as a ventricular septal defect or patent ductus arteriosus, result in turbulent flow. The development of stenosis or insufficiency across a native valve is another important contributing factor. Prosthetic devices, such as biologic or mechanical valves and synthetic grafts, are a common site for infection. Chronic indwelling catheters and pacemaker leads traumatize the chambers and valves, damaging the endocardial surface.

### Development of Nonbacterial Thrombotic Endocarditis

The subendocardium becomes exposed to the circulation after the endocardium has been damaged. The subendocardium is thrombogenic, and platelets and thrombi become adherent in an attempt to heal the breach in the endocardium. This accumulation forms into a mass, or vegetation, that either remains adherent or embolizes to varying degrees.

### Transient Bloodstream Infection

The vegetation is a susceptible area for colonization by infectious organisms. Typically, there is a transient bacteremia resulting in bacterial deposition on the NBTE vegetation. Such transient bacteremia is common after oral cavity manipulation, upper or lower gastrointestinal (GI) endoscopy, urinary tract instrumentation, and childbirth. Percutaneous interventions and untreated skin infections are also sources of bacteremia. More invasive procedures produce a higher degree of bacteremia, and a longer duration and degree of bacteremia will allow more bacteria to adhere to the vegetation.

### Adherence of Organisms to Nonbacterial Thrombotic Endocarditis

The vegetation becomes infected when bacteria or other organisms adhere to the NBTE. The ability of various organisms to adhere to the NBTE is variable. Gram-positive bacteria such as *Staphylococcus* and *Streptococcus*, for example, have a greater ability to adhere and form endocarditis than gram-negative bacilli.

The platelets in the NBTE also have a role in bacterial adherence. Certain strains of bacteria that more commonly cause endocarditis have been shown to bind to and activate platelets.[5] This may occur through the release of thrombin-induced platelet-microbicidal proteins (tPMPs) by activated platelets. Bacteria can directly activate platelets or result in thrombin formation, which is a platelet agonist.[6]

### Growth of the Vegetation

After deposition and adherence to the NBTE, the bacteria grow and multiply, enlarging the vegetation. Recurrent or persistent bacteremia can reseed the vegetation, also contributing to progressive growth. Gross examination of the vegetation demonstrates a mass of bacteria, platelets, and fibrin (Fig. 38-1).

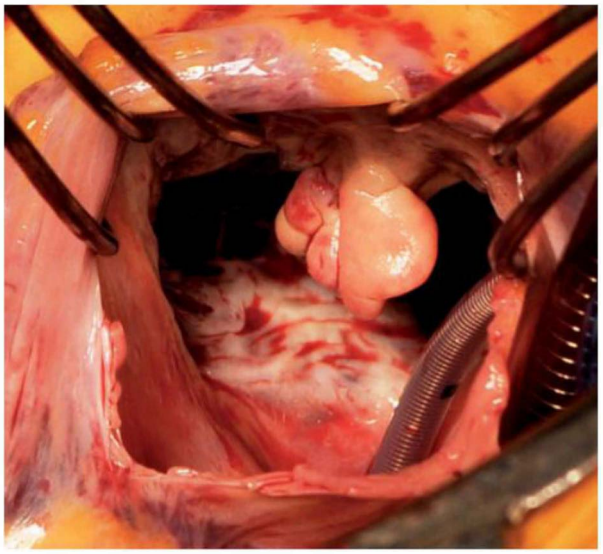

FIGURE 38-1 Vegetation on tricuspid valve exhibiting typical features of a mass of bacteria, fibrin, and platelets.

## EPIDEMIOLOGY

The overall incidence of IE in the general population ranges from 3 to 11 cases per 100,000 person-years.[7-9] About 75 percent of established cases occur in patients with an underlying structural defect of the heart.[10] Most commonly, these individuals have native valvular heart disease. Other common underlying conditions include previously implanted prosthetic valves and congenital heart disease. Endocarditis is more common in the elderly and males.[11]

Congenital heart disease represents a significant risk factor for the development of endocarditis. It has been estimated that the incidence of endocarditis in patients with any congenital heart defect is as high as 10 to 50 times the incidence of the general population. The most common congenital heart lesions associated with endocarditis are ventricular septal defect, transposition of the great arteries, tetralogy of Fallot, patent ductus arteriosus, and coarctation of the aorta. Those lesions with a cyanotic component are considered to be higher risk.

Mitral valve prolapse and bicuspid aortic valve are forms of congenital heart disease that most commonly present in older patients. The presence of a murmur is thought to be important to the development of endocarditis in these individuals, as the absence of a murmur is not associated with an increased prevalence in mitral valve prolapse.[12,13] Degenerative valve disease is also an important risk factor. The increasing use of indwelling intravenous catheters and leads for cardiac rhythm devices is associated with iatrogenic endocarditis.

## CLINICAL PRESENTATION

The clinical presentation of endocarditis depends upon the rapidity of onset, the virulence of the underlying organism, and the coexistence of underlying cardiac disease. More aggressive organisms in the setting of preexisting valvular disease will result in an accelerated course, with rapid diagnosis and early surgical intervention. Less virulent organisms may cause less destruction of cardiac structures, resulting in an elusive clinical course and prolonged illness.

### Acute Endocarditis

Patients with acute endocarditis usually present early in the infection with substantial illness. Findings include high fevers, chills, rigors, and malaise, with progression to sepsis and circulatory collapse if untreated. Complications are common (see following) due to the aggressive nature of the infection, particularly embolic phenomena. Valvular disease may be extensive with resultant congestive heart failure in otherwise healthy individuals.

### Subacute Endocarditis

The initial presentation in the subacute setting commonly occurs between 2 and 4 weeks after infection. The symptoms are milder and more subtle, with lower fevers and generalized malaise. Other symptoms include weight loss, myalgias, and fatigue, which can mimic malignancy or other chronic illness. If there has not been significant cardiac destruction, most symptoms will resolve on appropriate antibiotic therapy.

Many patients with subacute endocarditis will be diagnosed after a complication has arisen, such as an embolic neurologic event. Other complications of embolism include arterial insufficiency, abdominal pain (bowel or splenic infarction), visual changes (retinal artery occlusion), myocardial infarction (coronary artery occlusion), and hematuria (renal infarction). Multiple septic emboli to the lungs can present as recurrent pneumonia or chest pain from pulmonary infarction.

Two potentially lethal complications of subacute endocarditis are heart failure and intracranial hemorrhage. Although the infection may be successfully treated with antibiotics, the residual structural damage to the heart may progress to heart failure. Thus, a patient with "healed" endocarditis should not be considered cured unless the valvular and ventricular function is stable over a period of time. Mycotic aneurysms from septic emboli to the brain are usually asymptomatic, but can rupture and result in devastating intracranial hemorrhage.

### Prosthetic Valve Endocarditis

As with acute and subacute endocarditis, prosthetic valve endocarditis is classified according to time frame from

surgery. Early prosthetic valve endocarditis is defined as infection occurring within 60 days of operation, and is usually due to either intraoperative contamination or infection in the early postoperative period. Common organisms are skin colonizers and respiratory tract pathogens. The presentation is similar to acute endocarditis and is associated with complications after surgery. Late prosthetic valve endocarditis is defined as infection occurring after 60 days from operation and presents similar to subacute endocarditis. The offending organisms are the same as those with native subacute infections.

## Complications of Infective Endocarditis

The majority of patients with endocarditis will have developed complications, either as the initial presentation or during the course of the disease. The most common complications include congestive heart failure, abscess formation, and embolism. Other less common complications include pseudoaneurysm, mycotic aneurysm, fistula, and conduction disturbances.

Congestive heart failure is the most common cause of death and typically is caused by valvular destruction and insufficiency. Less common causes of congestive heart failure from endocarditis are coronary artery embolization with subsequent myocardial infarction, acute papillary muscle rupture, and valvular stenosis from very large vegetations. Patients with aortic valve disease are particularly prone to develop congestive heart failure.

Extension of the endocarditis process into surrounding myocardium results in abscess formation. This most commonly occurs with aortic valve involvement, forming a root abscess (Fig. 38-2). Mitral valve involvement can result in interventricular or interatrial abscess. Suspicion of abscess should be raised in patients with conduction abnormalities, pericarditis, congestive heart failure, and prosthetic valves. Transesophageal echocardiography (TEE) has the highest sensitivity for the detection of perivalvular abscess.[14] Echocardiographic criteria for abscess include aortic root thickness greater than 9 mm, perivalvular density greater than 14 mm in the septum, sinus of Valsalva aneurysm or fistula, and instability ("rocking") of a prosthetic valve.[15]

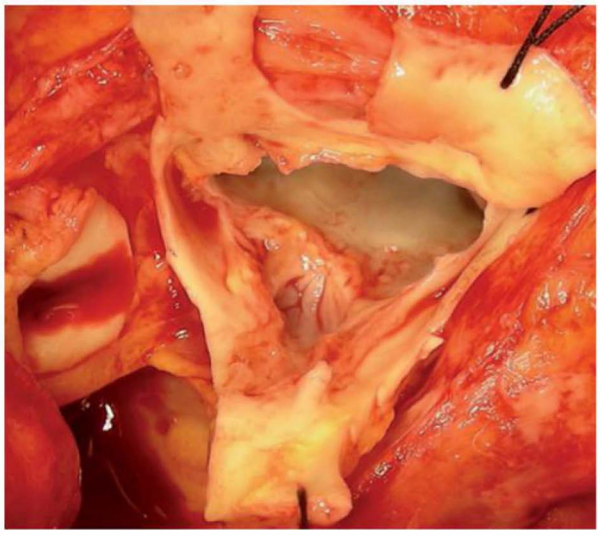

**FIGURE 38-2** Aortic root abscess. There is extension of the infection beyond the aortic annulus into the anterior leaflet of the mitral valve.

Embolism of the vegetation has the potential for significant morbidity and mortality, and is more common in younger patients.[16,17] Stroke occurs most commonly from native mitral valve endocarditis, as these lesions are usually larger than aortic valve vegetations.[18] In patients with prosthetic valve endocarditis, there is no difference in stroke rate between aortic and mitral valve involvement.[18] Predictors of stroke include left-sided endocarditis, mitral valve involvement, and size greater than 7 mm.[18]

Pseudoaneurysm occurs when the infective process liquefies and forms a cavity. Pulsatile pressure weakens the cavity and eventually blood enters the space, forming the pseudoaneurysm. The incidence of pseudoaneurysm ranges from 2 to 10 percent, and can occur in the setting of root abscess as well as along previous suture lines.[19] Rupture of pseudoaneurysm from IE is likely and requires prompt surgical attention.

Persistent bacteremia or embolization of infected vegetative material from the active endocarditis can result in metastatic abscess. Mycotic aneurysm occurs when a distant abscess forms in an arterial branch. Intracranial mycotic aneurysms typically form in the middle cerebral artery and can produce intracranial hemorrhage. Metastasis of infected material to other organs can result in splenic abscess, septic arthritis, and septic pulmonary embolism.

Fistula formation occurs when an abscess or pseudoaneurysm ruptures into a surrounding structure. Rupture into a cardiac chamber forms an intracardiac shunt, whereas rupture into the pericardium will produce tamponade. Although fistulas are rare, mortality exceeds 50 percent.[20]

Conduction abnormalities are the result of infective destruction of conduction tissue. First-degree atrioventricular block is most commonly observed.[21] Any new change in the electrocardiogram should raise the suspicion of abscess. Mortality can be increased in the presence of a conduction abnormality.[21]

## DIAGNOSIS

Although IE can be easy to recognize in a febrile patient with a new murmur, more commonly several physical and laboratory findings must be synthesized in order to establish an accurate diagnosis. In order to bring structure and validity to this process, Durack et al from Duke University proposed a set of diagnostic criteria in 1994. Modified by Li et al in 2000, these so-called "Duke criteria" are divided into *major* and *minor* categories.

Major criteria include positive blood cultures for IE, and evidence of endocardial involvement by echocardiography. Transesophageal echocardiography is recommended as a first test for patients with prosthetic valves, evidence of paravalvular abscess (e.g., new heart block), or a rating of at least "possible endocarditis" by clinical criteria. Transthoracic echocardiography is recommended in other patients. Minor diagnostic criteria include a predisposing condition (e.g., congenital heart disease or injection drug use), fever, evidence of embolic or immunologic phenomena, or equivocal microbiological findings.

The diagnosis of IE is established by the presence of two major criteria, one major and three minor criteria, or five minor criteria. Patients are diagnosed with "possible endocarditis" if they have one major and one minor criteria, or if they have three minor criteria. If a firm alternate diagnosis is established, or if a patient's symptoms resolve with less than 5 days of antibiotic therapy, the diagnosis of IE is rejected.

## History and Physical Examination

Adherence to the modified Duke criteria (Tables 38-1 and 38-2) during the initial evaluation provides the standard framework for establishing the diagnosis of endocarditis.[22–24] Important physical findings include cardiac murmurs, fever, signs of congestive heart failure, and peripheral manifestations. New or worsening murmurs signal valvular insufficiency. Fever is more common in patients with positive blood cultures.[25] Signs of congestive heart failure are important indicators of the severity of illness and possible need for early surgical intervention.

Peripheral manifestations of endocarditis include embolic, vascular and immunologic phenomena. Embolic arterial occlusion will result in diminished or absent pulses. Petechiae usually represent long-standing disease and are typically found in the conjunctivae, buccal mucosa, palate, and upper extremities. Osler nodes are small (0.5–1.5 mm), painful raised erythematous lesions found on the tips of the fingers and toes. In contrast, Janeway lesions are larger (2–5 mm), painless nodular erythematous lesions found on the palms of the hands and soles of the feet. Roth spots are oval-shaped hemorrhages on the retina with central pallor.

## Laboratory

There is no single laboratory test that is diagnostic for endocarditis. Multiple tests will support the diagnosis, including the presence of leukocytosis, anemia, elevated erythrocyte sedimentation rate, elevated c-reactive protein level, decreased serum complement levels, and presence of rheumatoid factor.

Blood cultures are the cornerstone laboratory test. In order to fulfill the Duke major criteria (Tables 1 and 2), the patient must have either a typical microorganism for IE isolated

**TABLE 38-1: Definition of Terms Used in the Proposed Modified Duke Criteria for the Diagnosis of Infective Endocarditis (IE)**

**Major criteria**
- Blood culture positive for IE
  - Typical microorganisms consistent with IE from two separate blood cultures:
    - Viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*; or
    - Community-acquired enterococci, in the absence of a primary focus; or
  - Microorganisms consistent with IE from persistently positive blood cultures, defined as follows:
    - At least two positive cultures of blood samples drawn >12 h apart; or
    - All of three or a majority of >4 separate cultures of blood (with first and last sample drawn at least 1 h apart)
  - Single positive blood culture for *Coxiella burnetii* or antiphase I IgG antibody titer >1:800
- Evidence of endocardial involvement
  - Echocardiogram positive for IE [TEE recommended in patients with prosthetic valves, rated at least "possible IE" by clinical criteria, or complicated IE (paravalvular abscess); TTE as first test in other patients], is defined as follows:
  - Oscillating intracardiac mass on valve or supporting structures, in the path of regurgitant jets, or on implanted material in the absence of an alternative anatomic explanation; or abscess; or new partial dehiscence of prosthetic valve
  - New valvular regurgitation (worsening or changing of preexisting murmur not sufficient)

**Minor criteria**
- Predisposition, predisposing heart condition or injection drug use
- Fever, temperature >38°C
- Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions
- Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor
- Microbiological evidence: positive blood culture but does not meet a major criterion as noted above[a] or serological evidence of active infection with organism consistent with IE

TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

[a]Excludes single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.

**TABLE 38-2: Definition of Infective Endocarditis (IE) According to the Modified Duke Criteria**

Definite IE
- Pathologic criteria
  1. Microorganisms demonstrated by culture or histologic examination of a vegetation that has embolized, or an intracardiac abscess specimen; or
  2. Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis
- Clinical criteria
  1. Two major criteria; or
  2. One major criterion and three minor criteria; or
  3. Five minor criteria

Possible IE
1. One major criterion and 1 minor criterion; or
2. Three minor criteria

Rejected
1. Firm alternate diagnosis explaining evidence of IE; or
2. Resolution of IE syndrome with antibiotic therapy for <4 days; or
3. No pathologic evidence of IE at surgery or autopsy, with antibiotic therapy for <4 days; or
4. Does not meet criteria for possible IE, as above

on two separate blood cultures or have persistently positive blood cultures drawn more than 12 h apart. In patients with unusual organisms, a single positive blood culture may be sufficient. More fastidious organisms or fungi may require several days or weeks to appear in the blood culture.

### Imaging

Plain chest radiography is nonspecific but important for associated findings of congestive heart failure. Cavitation or multiple infiltrates from septic pulmonary emboli may be identified. Computed tomography and magnetic resonance imaging (MRI) can be utilized to evaluate the complications of endocarditis, including stroke, mycotic aneurysm, and intra-abdominal processes. Cardiac MRI is particularly useful in complex valvular and abscess evaluation.

Echocardiography remains the diagnostic modality of choice for endocarditis. The hallmark is the vegetation, and echocardiography accurately defines the size, shape, and location of valvular vegetations. Intracardiac shunts, fistulae, and pseudoaneurysms can all be imaged with echocardiography.

TEE is superior to transthoracic echocardiography (TTE).[26] Specificity and sensitivity of TEE range from 88 to 100 percent and 86 to 100 percent, respectively.[27,28] The proximity of the TEE probe to the posterior wall of the heart provides better resolution, improved visualization of prosthetic valves, superior characterization of mitral valve disease, and finer assessment of abscess and fistula. Although TEE is more invasive and more expensive, it provides the optimal method for establishment of endocarditis according to the Duke major criteria.

In patients with a high likelihood of IE, TTE is usually sufficient to establish the diagnosis.[29] Similarly, TTE is technically adequate to establish a negative diagnosis in patients with a low likelihood of endocarditis.[29] Patients with an intermediate likelihood of endocarditis will have the most benefit from TEE, allowing for the definitive diagnosis.[29] TEE should be performed in every patient prior to operation unless contraindicated.

## MEDICAL THERAPY

Prompt and accurate antimicrobial therapy should be initiated for the patient with endocarditis. Ideally, this is instituted after the initial blood cultures have been obtained, and subsequent therapy is modified according to antibiotic sensitivities. The American Heart Association guidelines provide recommended antibiotic selections for various organisms and should be routinely consulted to guide therapy.[30,31] In general, antibiotic therapy will be administered intravenously in high dosages for a prolonged period of time. Drug resistance has become common and an experienced infectious disease consultation is advised.

Empiric antibiotics can be started and guided according to suspected organisms in specific patients. A combination of penicillin and gentamicin is reasonable, as this regimen will treat most of the common organisms. Suspicion of *Staphylococcus* will require substitution of a penicillinase-resistant agent such as nafcillin. Ampicillin may be added to cover the HACEK organisms. Intravenous drug users are susceptible to methicillin-resistant *Staphylococcus aureus*, and vancomycin and gentamicin are appropriate as initial therapy. Antifungal therapy should be considered in this population and any patient with critical illness that is not improving on standard antibiotic regimens, as these patients are at risk for fungal endocarditis.

## SURGICAL THERAPY

The primary goals of operation for endocarditis are removal of all infected tissue and correction of the hemodynamic abnormality. Inadequate drainage of infection results in a high probability of reinfection and subsequent complications. Infection of a cardiac valve necessitates either repair or replacement, and the surgeon must ensure that the surrounding tissue is healthy and viable in order to support any prosthetic material.

### Aortic Valve Disease

In general, endocarditis that affects the aortic valve will require valve replacement. It is the unusual patient that will have a small, localized perforation of a valve leaflet that

will be appropriate for patch reconstruction. Most patients will have destruction of the leaflets, which render the native valve unsuitable for repair, and replacement is indicated. There is no conclusive evidence to suggest that tissue bioprostheses have an advantage over mechanical prostheses for preventing reinfection.[31] Some recommend soaking the prosthetic valve in antibiotics or irrigating the area with antiseptic solutions.[32] After removal of the infected leaflets and debridement of the annulus, the new valve is inserted in standard fashion.

Careful inspection of the aortic root and anterior leaflet of the mitral valve should be performed simultaneously to evaluate for aortic root abscess or drop lesions on the mitral valve. All infected and necrotic tissue at the root must be removed. Stentless tissue valves, either xenografts or allografts, are more pliable than mechanical composite grafts and are useful to reconstruct continuity between the left ventricular outflow tract and the ascending aorta. It is important to be certain that the proximal suture line is well-seated in the left ventricular outflow tract, as this will exteriorize all infected tissue outside the blood stream.

Extension of the infection from the aortic root into the anterior leaflet of the mitral valve requires simultaneous reconstruction of the root and the mitral valve. This is accomplished with an allograft, keeping the attached anterior mitral leaflet intact. After removal of the root and construction of coronary buttons, the mitral valve is debrided. The retained allograft mitral leaflet is attached with running polypropylene suture to fill the defect in the mitral valve. The remainder of the allograft root is attached to the left ventricular outflow tract and the coronary buttons are reimplanted.

## Mitral Valve Disease

The mitral valve lends itself more often to reparative procedures. Perforations can be repaired with pericardial patch reconstruction (Fig. 38-3A). Destruction of the P2 segment of the posterior leaflet can be repaired with limited resection and sliding valvuloplasty, followed by posterior annuloplasty to support the repair (Fig. 38-3B). Drop lesions on the chordae tendineae can be carefully removed.

The presence of severe mitral insufficiency in the setting of endocarditis dictates valve replacement. Careful inspection is performed to evaluate for the presence of ventriculoatrial discontinuity. If there is annular abscess, all infected tissue must be removed. The annulus is reconstructed using a sheet of pericardium as a "bridge" between the ventricle and the atrium (Fig. 38-4A–C). The new valve is then secured to the ventricular aspect of this patch with pledgetted sutures.

## Tricuspid Valve Disease

The tricuspid valve can be repaired in nearly every patient with endocarditis. Patch closure of a perforation is performed in a similar manner to mitral valve perforations. More liberal leaflet excision can be accomplished on the tricuspid valve, and should be supported with complete annuloplasty.

## Sinus of Valsalva Fistula

Infection of the aortic valve with subsequent perforation of a sinus of Valsalva fistula can occur. After removal of all infected tissue, the fistula is explored. This may require opening of the secondary cardiac chamber for adequate visualization and debridement of additional infection. The fistula is closed with a pericardial patch and the aortic valve or root reconstructed as indicated.

## SURGICAL OUTCOMES

Mortality after operation for endocarditis ranges widely, with reports of hospital death between 4 and 30 percent.[33–36] In general, operative mortality is affected by the urgency of the operation, with emergency operations carrying the highest risk.[37] Concomitant preoperative heart failure and other comorbidities also have a negative impact on operative mortality.[37] Nonstreptococcal organisms and prosthetic valve endocarditis also are associated with increased mortality.[37] More complex operations, however, do not seem to adversely affect outcomes.[33,38] Late survival after operations for endocarditis are not as good as operations performed for other types of valvular disease.[39,40]

Heart block is more common after operation in patients with endocarditis than in those without infection. This is often predictable due to the extensive removal of infected tissue that may be required. A new or worsening neurologic deficit can be devastating and is most often due to aggravation of an existing central nervous system event. It is important to identify such preoperative findings and whether there is associated intracranial hemorrhage, as this worsens with anticoagulation during surgery. The risk of exacerbation of a neurologic deficit is highest if surgery is required within 1 week (44–46 percent), falls to 10 percent after 2 weeks, and declines further to 2 percent after 4 weeks.

Recurrent endocarditis is uncommon (2–5 percent) if all infected tissue has been removed and there is no active infection at the time of operation. Reinfection is more common if the organism is nonstreptococcal, there is a root abscess, or the patient is an intravenous drug abuser. For aortic native valve endocarditis, there is some evidence to suggest that replacement with an aortic allograft confers the best freedom from reinfection.[22,36] For all other types of native and prosthetic valve endocarditis, there is no evidence to suggest one type of prosthetic valve over another.

## SURGICAL TREATMENT OF ENDOCARDITIS BOARD REVIEW QUESTIONS (CHAPTER 38)

1. Which of the following is *not* a major Duke criterion for the diagnosis of endocarditis?
   A. Two separate blood cultures positive for *Streptococcus bovis*
   B. Persistently positive blood cultures drawn 6 h apart
   C. Oscillating intracardiac mass on valve
   D. New valvular regurgitation
   E. Single positive blood culture for *Coxiella burnetii*

2. Which is correct regarding the pathogenesis of endocarditis?
   A. Damage occurs to the epicardial surface of a cardiac structure.
   B. There is accumulation of thrombus and platelets on the damaged surface.
   C. The patient develops a transient bloodstream infection.
   D. Infectious organisms deposit on the nonbacterial thrombotic focus.
   E. Organisms multiply at the infected site.

3. Which is correct regarding the clinical presentation of endocarditis?
   A. Acute endocarditis occurs up to 4 weeks after infection.
   B. Complications are more common in subacute endocarditis.
   C. Most symptoms resolve with appropriate antibiotic therapy in the subacute setting.
   D. Most mycotic aneurysms are symptomatic.
   E. Late prosthetic endocarditis is usually due to intraoperative contamination.

4. Which of the following is correct regarding complications of endocarditis?
   A. The minority of patients actually develop complications.
   B. The most common cause of congestive heart failure is coronary artery embolization.
   C. Embolism is more common in the elderly.
   D. Stroke is most common from a mitral valve vegetation.
   E. Rupture of a pseudoaneurysm is unlikely.

5. Which of the following is true for outcomes after surgery for endocarditis?
   A. Emergency operations do not have increased risk.
   B. Concomitant heart failure increases operative risk.
   C. Streptococcal organisms are associated with higher mortality.
   D. More complex operations result in higher complication rates.
   E. Mechanical valves are less likely to become reinfected.

## ANSWERS

1. **Answer: B.** Persistently positive blood cultures must be 12 hours apart to be considered a major criterion. Two separate blood cultures positive for *Streptococcus bovis*, an oscillating intracardiac mass on a valve, new valvular regurgitation, and a single positive blood culture for *Coxiella burnetii* are all considered major criteria.
2. **Answer: A.** Damage occurs to the endocardial, not epicardial, surface of a cardiac structure. After the damage occurs, there is accumulation of thrombus and platelets on the damaged surface (NBTE). The patient develops a transient bloodstream infection, usually bacterial, and these organisms deposit on the focus of the nonbacterial thrombotic area. Finally, organisms multiply at the infected site.
3. **Answer: C.** Most patients with subacute endocarditis will have resolution of symptoms with appropriate antibiotic therapy. Acute endocarditis is defined as occurring within 2 weeks of infection. Complications are more common in acute endocarditis. Most mycotic aneurysms are asymptomatic. Late prosthetic endocarditis is caused by the same organisms as native infections.
4. **Answer: D.** Stroke occurs mostly commonly from mitral valve vegetations, which tend to be larger and more mobile. The majority of patients develop complications from endocarditis. The most common cause of congestive heart failure is valvular insufficiency. Embolism is more common in the younger population. Rupture of a pseudoaneurysm from infection is likely and warrants prompt surgical intervention.
5. **Answer: B.** Concomitant heart failure is associated with increased operative risk, as are emergency operations and nonstreptococcal organisms. More complex operations do not adversely affect outcomes. There is no difference between mechanical and biologic prostheses for reinfection rates.

# Ascending and Arch Aneurysms of the Aorta

*Anthony D. Caffarelli*
*Pieter J. A. van der Starre*
*R. Scott Mitchell*

***"There is no disease more conducive to clinical humility than aneurysms of the aorta."***

—Sir William Osler

## KEY CONCEPTS

- Epidemiology
  - The leading cause of aneurysms of the ascending aorta is medial degeneration, which may be idiopathic or accelerated by heritable disorders of connective tissue; conversely, arch aneurysms are due to chronic dissection or long-standing hypertension and atherosclerosis.
- Pathophysiology
  - Histopathologic investigations of aneurysmal tissue have shown that a majority of ascending aortic and arch aneurysms are associated with medial degeneration in the layers of the aortic wall. This is characterized by a triad of (1) loss of noninflammatory smooth muscle cells, (2) fragmentation of elastic fibers, and (3) accumulation of basophilic ground substance in cell-depleted areas of the medial layer of the vessel wall. This combination of factors weakens the aortic wall, thereby increasing wall tension; this can induce aortic dilatation and aneurysm formation, leading to higher wall stress and eventually resulting in intramural hemorrhage, aortic dissection, or rupture. Medial degeneration can be accelerated by inborn errors of metabolism that affect any component of the aortic connective tissue. Known heritable disorders of connective tissue that commonly manifest as ascending and arch aneurysms of the aorta are Marfan syndrome, Ehlers–Danlos syndrome, Loeys–Dietz syndrome, familial forms of thoracic aortic aneurysm and dissection, and bicuspid aortic valve disease; Turner syndrome and Noonan syndrome occur far less frequently.
- Clinical features
  - Most patients with thoracic aortic aneurysms are asymptomatic at the time of presentation, and aneurysms of the ascending aorta usually are detected as incidental findings during testing for other disorders. In contrast, because of their anatomic location and the space-occupying nature of the aneurysm, aneurysms of the aortic arch may impinge on important mediastinal structures and are therefore symptomatic more often than aneurysms of the ascending or descending aorta. Symptoms attributable to the aneurysm are cause for concern and consideration for early surgical intervention. Patients with rupture of an ascending or arch aneurysm often present in extremis.
- Diagnostics
  - The most common finding on chest x-ray for a thoracic aortic aneurysm is widening of the superior mediastinum; other findings include displacement and compression of the mediastinal contents and curvilinear calcification in the aneurysmal wall. Echocardiography is widely available, can be noninvasive [transthoracic echocardiography (TTE)] or minimally invasive [transesophageal echocardiography (TEE)], and is relatively inexpensive. TTE can visualize the aortic root and ascending aorta accurately and is suitable for evaluating the size of moderate aneurysms and assessing cardiac complications such as aortic regurgitation (AR), impaired left ventricular function, and hemopericardium. Intraoperative application of TEE allows continuous monitoring of the surgical procedure without disturbing the sterile field. Because of its speed and wide availability, computed tomography/computed tomography angiography (CT/CTA) is currently the most common diagnostic

imaging method for studying the aorta. CTA has the advantage of demonstrating aortic wall thickening, calcification, and luminal thrombus, thus displaying the true axial extent of an aneurysm. Magnetic resonance angiography is emerging as a diagnostic tool but is less readily available and has limited utilization in acute aortic problems because of its limited applicability.

- Treatment
  - Symptomatic patients with ascending or arch aneurysms should be evaluated urgently for surgical repair. Patients presenting with rupture should be operated on urgently, since these conditions are almost uniformly fatal without prompt surgical intervention. Operative intervention in a patient with a non-heritable connective tissue disorder should be considered when the ascending aortic aneurysm diameter ranges from 5 to 5.5 cm. For patients with an aneurysm diameter less than 5 cm who are being monitored with serial imaging, an indication for surgical intervention would be a 10 percent increase in size over a 6- to 12-month time course. For patients with a heritable disorder of connective tissue, surgical intervention for the ascending aorta should be considered at a diameter of 4 cm for Loeys–Dietz syndrome, 4 to 4.5 cm for Marfan syndrome, 4.5 to 5.0 cm for bicuspid aortic valve, and 5.0 cm for Ehlers–Danlos syndrome. Factors that prompt the recommendation for surgery when the aorta is less than 5.0 cm include rapid growth of the aortic diameter (more than 1 cm/year), a family history of premature aortic dissection (dissection at less than 5.0 cm), and the presence of moderate or severe AR. Operative repair varies with the underlying pathology and the quality of the aortic wall, the status of the aortic valve, expected survival, and the general well-being of the patient.
- Outcomes
  - Progress over the past three decades, including improved surgical instrumentation and advances in perfusion strategies with resultant improvements in myocardial and cerebral protection have augmented the surgical armamentarium significantly, facilitating the management of complex aortic problems. Replacement of the ascending aorta is a safe and effective procedure, with operative mortality rates of 2 to 5 percent. The operative mortality varies with the acuity of the operation, patient age, left ventricular function, and extent of operation. Late survival after operation is approximately 65 percent at 5 years and 55 percent at 7 years. For patients with Marfan syndrome, a valve-sparing aortic root replacement is a reasonable alternative to a composite valve graft. Survival is excellent with reimplantation and remodeling techniques and complications are rare, but the long-term durability of these repairs have not been established. For aortic arch replacement, the average operative mortality rate is 13 percent, with long-term survival ranging from 61 to 82 percent at 5 years and 31 to 69 percent at 10 years. Despite these advances, providing adequate cerebral protection and preventing cerebral embolization during reconstruction of the calcified and atherosclerotic aorta are formidable challenges.

# INTRODUCTION

Surgical repair of ascending and arch aneurysms of the aorta is one of the most formidable challenges facing the cardiovascular surgeon. The challenges stem from the often-catastrophic consequences of rupture of the thoracic aorta, the variegated clinical presentations associated with aortic disruption, and the risk of incurring devastating neurologic injury during aortic arch repair. This chapter describes the epidemiology, pathophysiology, clinical features, diagnosis, treatment, and outcomes of ascending and arch aneurysms of the aorta.

## Definitions

A *true* aortic aneurysm is defined arbitrarily as a 50 percent enlargement of the normal aorta for a particular body surface area, age, and gender.[1] Clinically, the term usually is reserved for ascending aortic (sinus or tubular) diameters greater than 3.5 to 4.0 cm or aortic arch diameters greater than 4 cm. Some experienced thoracic aortic surgical centers use a ratio of 2× in which the diameter of the enlarged aortic segment is in the numerator and that of the normal contiguous aorta is in the denominator.[2] The combination of dilation of the ascending aorta and dilation of the aortic annulus is termed *annuloaortic ectasia*.[3] A *false* aortic aneurysm is a localized dilation whose wall consists of adventitia, some or all of the media, and compressed periaortic tissue usually associated with trauma, infection, or previous operations on the aorta. The classification of thoracic aortic aneurysms is based on the location, morphologic characteristics, or etiology.[4]

### CLASSIFICATION ACCORDING TO LOCATION

The location of the aneurysm affects clinical manifestations, natural history, and treatment options as well as providing insight into the etiology of the aneurysm formation. Thoracic aortic aneurysms can involve the ascending aorta, the arch, or the descending aorta. The ascending aorta is the portion of aorta starting at the aortic annulus and ending at the origin of the innominate artery near the pericardial reflection. The ascending aorta is separated further into a

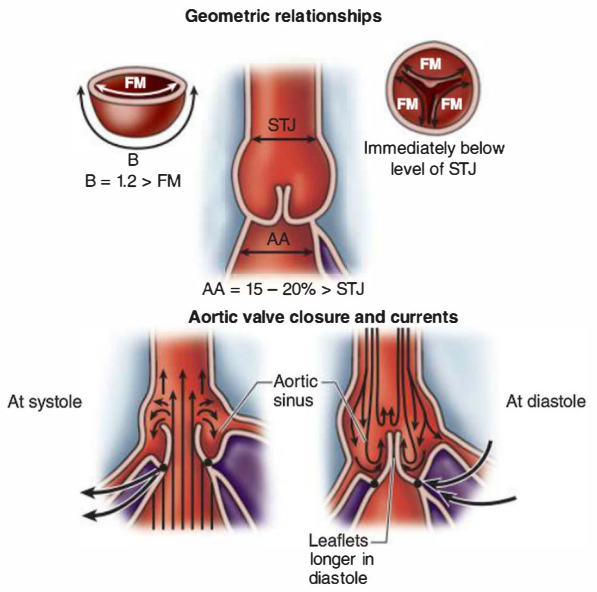

**FIGURE 39-1** The static and basic functional anatomy of the aortic root-valve complex. Note that the sinotubular junction diameter is approximately 15 percent less than that of the base of the aorta (putative aortic annulus). The DaVinci sinus currents are depicted; they enhance leaflet closure at the end of systole and protect leaflets from wall impact during systole. In addition, movement of the annulus changes the tension–length relationships of the leaflets to enhance function. It is difficult to demonstrate in a two-dimensional figure the time-dependent expansion of the aortic root that occurs during the first third of systole and the change in its overall configuration from a truncated cone shape with acorn protuberances of the sinuses to a larger, more cylindric form that would offer less impedance to ejection. FM, free margin; B, base of semilunar leaflet insertion; STJ, sinotubular junction; AA, aortic annulus (defined as the base of the aorta, not the semilunar leaflet attachment scalloped edge). (Reproduced, with permission, from Hopkins RA. Aortic valve leaflet sparing and salvage surgery: Evolution of techniques for aortic root reconstruction. *Eur J Cardiothorac Surg* 2003;24(6):886–897.)

proximal sinus portion, also known as the aortic root, and a distal tubular portion, with the demarcation line occurring at the sinotubular junction (STJ), which is at the top of the aortic valve commissures (Fig. 39-1). These distinctions are important in that operations involving the aortic root require repair or replacement of the aortic valve and reimplantation of the coronary arteries. The aortic arch begins at the proximal origin of the innominate artery, traverses in conjunction with the brachiocephalic vessels, and ends at the distal origin of the left subclavian artery, dividing the aortic arch into the proximal, transverse, and distal sections, respectively. Aneurysms of the descending thoracic aorta originate distal to the origin of the left subclavian artery, whereas thoracoabdominal aneurysms originate in the descending thoracic aorta and extend below the diaphragm to involve various extents of the abdominal aorta.

### CLASSIFICATION ACCORDING TO MORPHOLOGY

The gross pathoanatomic description of thoracic aortic aneurysms includes fusiform and saccular aneurysms. Fusiform aneurysms involve a long segment of the aorta with uniform dilation involving the whole circumference of the aortic wall, whereas saccular aneurysms usually involve only a localized segment of the aorta with an eccentric dilation that communicates with the main lumen of the aorta by a variable-sized neck.[4]

### CLASSIFICATION ACCORDING TO ETIOLOGY

Classification by etiology provides the most meaningful nomenclature for thoracic aortic aneurysms because of the treatment implications but at the same time is the most difficult to do. This stems from the variety of causes of thoracic aortic aneurysms, which histologically look very similar. The leading cause of aneurysms of the ascending aorta is medial degeneration, which may be idiopathic or accelerated by heritable disorders of connective tissue; conversely, arch aneurysms are due to chronic dissection or long-standing hypertension and atherosclerosis. This is discussed in more detail in the pathophysiology section.

## Historical Highlights

The first description of arterial aneurysms is attributed to Galen, who observed false aneurysms in gladiators injured during battle in the second century. During that period, Antyllus made the distinction between traumatic and degenerative aneurysms and was the first to attempt surgical treatment of aneurysms with proximal and distal ligation.[5] In 1557, Vesalius[6] was credited with the first correct clinical diagnosis, and Morgagni outlined fascinating and detailed case histories, postmortem findings, and commentaries on three cases of ruptured thoracic aneurysms in young adults in 1769. In his great work *The Seats [Sites] and Causes of Diseases*, he described the graphic case report of a "strumpet [prostitute] of eight-and-twenty years of age" who died suddenly in the act of performing her profession, causing considerable embarrassment to her client.[7]

The early operative treatment of thoracic aneurysms was entirely palliative, consisting of the introduction of wire within the sac to stimulate clot formation or the wrapping of cellophane around the sac to induce periarterial fibrosis. Before the availability of cardiopulmonary bypass (CPB), surgical treatment of thoracic aortic aneurysms was limited to resection of discrete saccular aneurysms associated with coarctations.[7] Even though the first isolated thoracic aneurysm of the arch was resected by Monod and Meyer in Paris in 1950,[8] the development of current aortic surgery procedures was contingent on improvements in vascular surgical instruments and the evolution of arterial grafts and bypass procedures in conjunction with CPB and the various perfusion techniques.

### ASCENDING ANEURYSMS

Cooley and DeBakey[9] are credited with the first resection of an ascending aortic aneurysm and replacement with a graft in 1956; subsequently, a variety of approaches evolved. In 1960, Mueller and colleagues[10] combined supracoronary graft replacement with bicuspidization of an incompetent aortic valve. In 1963, Starr and associates[11] described supracoronary graft replacement and replacement of the aortic valve. In 1964, Wheat and coworkers[12] described a technique of radical resection of the aortic wall that left small buttons of tissue adjacent to the coronary ostia, replacement of the aorta with a graft, and prosthetic replacement of the aortic valve. Bentall and DeBono[13] and, independently, Edwards and Kerr[14] introduced a method of replacing the aortic valve and ascending aorta simultaneously using a composite valve graft (CVG) and reimplanting the coronary ostia into the graft. After 1968, the CVG procedure evolved to include full-thickness end-to-side coronary anastomoses in the form of Carrel "buttons" of aorta and a full-thickness end-to-end distal aortic anastomosis rather than the original "wrap inclusion" or Bentall technique.[2]

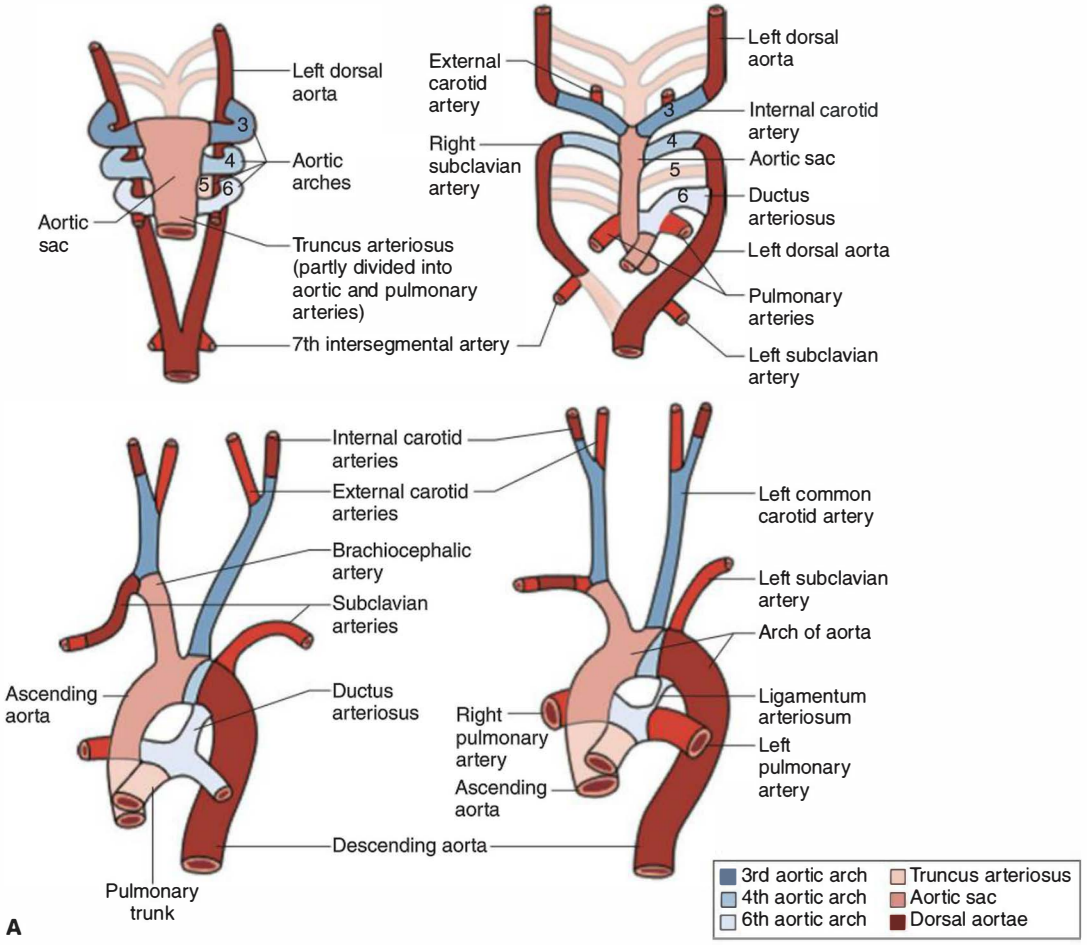
### ARCH ANEURYSMS

Resection of aortic arch aneurysms has remained a more formidable surgical challenge. In 1957, DeBakey and colleagues[15] reported the first successful replacement of an ascending and arch aneurysm with an aortic homograft, using CPB with separate innominate and left common carotid artery perfusion. Bloodwell and associates[16] modified the basic CPB technique in 1968 to perfuse the carotid and vertebral arteries separately and implant the arch vessels together as a single "button." Griepp and associates[17] at Stanford first used the technique of circulatory arrest for complete replacement of the aortic arch in 1975 with implementation of the "open distal." In 1983, the "elephant trunk" technique was introduced by Borst and associates[18] as an alternative for the treatment of patients with extensive aortic aneurysmal disease involving the arch and the descending or thoracoabdominal aorta.

## Basic Embryology and/or Anatomic Considerations

At one stage of development, two aortic arches (right and left) are present with normal development, including persistence of the left arch and involution of the right arch. Originating from the aortic arch are branching vessels, with many variations in both the number and the position of those vessels. Permutations may be as few as one or as many as six branches, with these anomalies intimately associated with the development of the fourth arterial arches (Fig. 39-2A). In about 80 percent of people, the branching order is innominate, left common carotid, and left subclavian; however, in 11 percent of these patients, a bovine arch exists where the innominate and the left common carotid have a common ostia and the left subclavian arises independently from the arch (Fig. 39-2B).[19,20] Aberrant right subclavian artery (ARSCA) affects approximately 0.1 percent of the population and is often an incidental finding on imaging studies. It occurs when the right fourth aortic arch and the right dorsal aorta involute cranial to the seventh intersegmental artery.[21] The ARSCA arises from the descending aorta or a diverticulum and crosses to the right behind the esophagus (Fig. 39-2C). Surgeons must be aware of the possible variations in the great vessels arising from the aortic arch because misidentification during surgery could be catastrophic.

# PATHOPHYSIOLOGY



## Introduction

The aortic wall is organized into three distinct layers: the intima, media, and adventitia (Fig. 39-3). The media of the aorta is composed of smooth muscle cells within a matrix of elastin, collagen, and other structural proteins, including fibrillin, laminin, glycosaminoglycans, proteoglycans, and fibronectin. The overall strength of the aortic wall is determined by the relative amounts of elastin and collagen; elastin conveys the arterial recoil capabilities, and collagen provides the necessary structural strength. Defects in either protein can cause aortic pathology.[22] Table 39-1 lists the etiologies of thoracic aortic aneurysms; these entities and their clinical implications are described in the following section.

## Medial Degeneration

### IDIOPATHIC MEDIAL DEGENERATION

Histopathologic investigations of aneurysmal tissue have shown that the majority of ascending aortic and arch aneurysms are associated with medial degeneration in the layers of the aortic wall.[23,24] These degenerative changes within the aortic media, which historically and incorrectly were called medial necrosis or cystic medial necrosis,[25] are characterized by a triad of (1) loss of non-inflammatory smooth muscle cells, (2) fragmentation of elastic fibers, and (3) accumulation of basophilic ground substance in cell-depleted areas of the medial layer of the vessel wall. This combination of factors first weakens the aortic wall, thereby increasing the wall tension, which can induce aortic dilatation and aneurysm formation. In turn, this leads to higher wall stress, eventually resulting in intramural hemorrhage, aortic dissection, or rupture. Medial degeneration occurs normally to some extent with aging, but the process is accelerated by hypertension.[26] In addition, turbulent flow within the aneurysm cavity frequently leads to the formation of laminated thrombus and further atherosclerotic depositions in the aortic wall. The thrombus lining and aortic calcifications, although often substantial, convey no added strength for the prevention of rupture.[22]

## HERITABLE DISORDERS OF CONNECTIVE TISSUE

Medial degeneration is accelerated by inborn errors of metabolism that affect any component of the aortic connective tissue (i.e., ground substance, collagen, elastin, or smooth muscle cells). Known heritable disorders of connective tissue that commonly manifest as ascending and arch aneurysms of the aorta are Marfan syndrome (MFS), Ehlers–Danlos syndrome (EDS), Loeys–Dietz syndrome (LDS), familial forms of thoracic aortic aneurysm and dissection, and bicuspid aortic valve (BAV) disease; Turner syndrome and Noonan syndrome occur far less frequently.

**TABLE 39-1: Etiology of Ascending and Arch Aortic Aneurysms**

Medial degeneration
- Idiopathic degeneration
- Heritable disorders of connective tissue
  - Marfan syndrome (MFS)
  - Ehlers–Danlos syndrome (EDS)
  - Loeys–Dietz syndrome
  - Familial thoracic aortic aneurysms and dissections (TAAD)
  - Bicuspid aortic valve (BAV)
  - Turner and Noonan syndromes

Infection
- Mycotic aneurysms
- Syphilitic aneurysms

Inflammatory
- Takayasu arteritis
- Behçet disease
- Giant cell arteritis

Chronic aortic dissection

***Marfan Syndrome.*** Among hereditary diseases, MFS is the most prevalent inherited connective tissue disorder, with a prevalence of approximately 1 in 3000 to 5000 individuals. The diagnosis is clinical, relying on the revised Ghent consensus criteria.[27] The condition is inherited in an autosomal dominant manner with complete penetrance but demonstrates variable expression with significant intra- and interfamilial variation (Fig. 39-4).[2] More than 100 mutations have been identified in the fibrillin-1 gene on chromosome 15, as well as more recently identified missense mutations in the transforming growth factor β (TGF-β) gene, which encodes for the TGF-receptor. As a result, defective coding of fibrillin, the major structural component of elastin, occurs as well as excessive TGF-β activity. The consequence is both a decrease in the amount of elastin in the aortic wall and a loss of the normally highly organized structure of elastin (Fig. 39-5). In addition, Marfan aortic tissue has enhanced expression of metalloproteinases, which may promote both fragmentation of medial elastic layers and elastolysis.[28] The end result is an aorta that exhibits markedly abnormal elastic properties that lead to progressive increases in stiffness and dilation. Additional cardiovascular complications include mitral valve prolapse and regurgitation and left ventricular dilation, but aortic root dilation is the most common cause of morbidity and mortality.

***Ehlers–Danlos Syndrome.*** EDS is a rare autosomal dominant inherited disorder of connective tissue that results from mutations in the *COL3A1* gene, which encodes for type III collagen on chromosome 2. The classification of EDS has been simplified into six major types, including vascular EDS (formerly known as type IV EDS), which carries a substantial risk of rupture of the aorta and its major branches.[29] Arteries in the thorax and abdomen account for 50 percent of the vascular complications,[30] but any anatomic location can be involved, with a predilection for medium-size arteries.

***Loeys–Dietz Syndrome.*** The LDS is a recently described autosomal dominant aortic aneurysm syndrome that has widespread systemic involvement.[31] A spectrum of mutations in transforming growth factor β receptors 1 and 2 (*TGFBR1* or *TGFBR2*, respectively) cause the LDS, which histologically results in a loss of elastin content and disarrayed elastic fibers in the aortic media.[32] The phenotype of LDS overlaps with that of MFS (aortic aneurysm, arachnodactyly, dural ectasia), but it also includes distinctive features such as widely spaced eyes (hypertelorism), bifid uvula and/or cleft palate, and generalized arterial tortuosity. The natural history of LDS differs considerably from other connective tissue disorders with the average age at a first cardiovascular event much lower than that for patients with untreated MFS or vascular EDS, suggesting that mutations

| Criterion | Major | Minor |
|---|---|---|
| **Skeleton system** | | |
| Manifestations | Pectus carinatum or pectus excavatum surgery, arm span to height ratio >1.05 or reduced US/LS* <0.86 (adults), positive wrist and thumb sign, scoliosis >20° or spondylolthesis, limited elbow extension (<170°), pes plaxus | Facial appearance, joint hypermobility, pectus excavatum of moderate severity, highly arched palate |
| Involvement | 4 of 7 present | 2 of 7 major present, or 1 of 7 major and 2 of 4 minor present |
| **Ocular system** | | |
| Manifestations | Ectopia lentis | Myopia, flat cornea, iris or ciliary muscle hypoplasia |
| Involvement | Ectopia lentis present | 2 of 3 minor present |
| **Cardiovascular system** | | |
| Manifestations | Dilation of ascending aorta with or without aortic regurgitation and involving sinuses of Valsalva, dissection of ascending aorta | Mitral valve prolapse, annulus mitralis calcification (age of onset, <40 y), pulmonary artery dilation, dilatation or dissection of descending thoratic or abdominal aorta (age of onset, <50 y) |
| Involvement | 1 of 2 present | 1 of 4 minor present |
| **Pulmonary system** | | |
| Manifestations | | Pneumothorax, apical blebs (chest radiography) |
| Involvement | | 1 of 2 minor present |
| **Skin** | | |
| Manifestations | | Striae atrophicae (not associated with weight changes or pregnancy), recurrent or incisional hernias |
| Involvement | | 1 of 2 minor present |
| **Dura** | | |
| Manifestations | Lumbossoral dural ectasia bt CT or MRI | |
| Involvement | Dural ectasia present | |
| **Family** | | |
| Involvement | First-degree familiy member independently fulfilling diagnostic criteria, mutation in *FBNI* known to cause MPS | |

*US/LS indicates ratio of upper segment to lowe segment.

**FIGURE 39-4** Diagnostic criteria according to the Ghent nosology (From Milewicz DM, Dietz HC, Miller DC. Treatment of aortic disease in patients with Marfan syndrome. *Circulation* 2005 22;111(11):e150–e157. With Permission).

in *TGFBR1* or *TGFBR2* predispose to more aggressive and widespread vascular disease.

***Familial Thoracic Aortic Aneurysms and Dissections.*** It is coming to be known that patients without genetic syndromes such as MFS or EDS also manifest familial clustering of thoracic aortic aneurysms and dissections (TAAD). In the Yale database of over 1600 patients, detailed family trees of 300 families revealed that 21 percent of aneurysm probands have a first-order relative with a known or likely aortic aneurysm.[33] Most pedigrees suggest an autosomal dominant mode of inheritance, but there is marked variability in the expression and penetrance of the disorder in which some inherit and pass on the gene but show no manifestation of the disease. These nonsyndromic patients have been studied, and to date three genomic loci for nonsyndromic familial TAAD have been elucidated: the TAAD1 locus mapped to the long arm of chromosome 5, with approximately half of the identified families mapping to this locus; the FAA1 locus on the long arm of chromosome 11, which is responsible for aneurysmal disease in one large family; and the MFS2 locus on chromosome 3, which is a rare cause of familial TAAD.[4] Therefore, TAAD is now a recognized heritable disorder of connective tissue.

***Turner and Noonan Syndromes.*** Turner syndrome is a sex aneuploidy syndrome in which the most common chromosome constitution is 45-X0; it has an incidence of 1 in 5000 live female births. The cardiovascular problems include BAV (present in one-third of subjects), coarctation of the aorta,

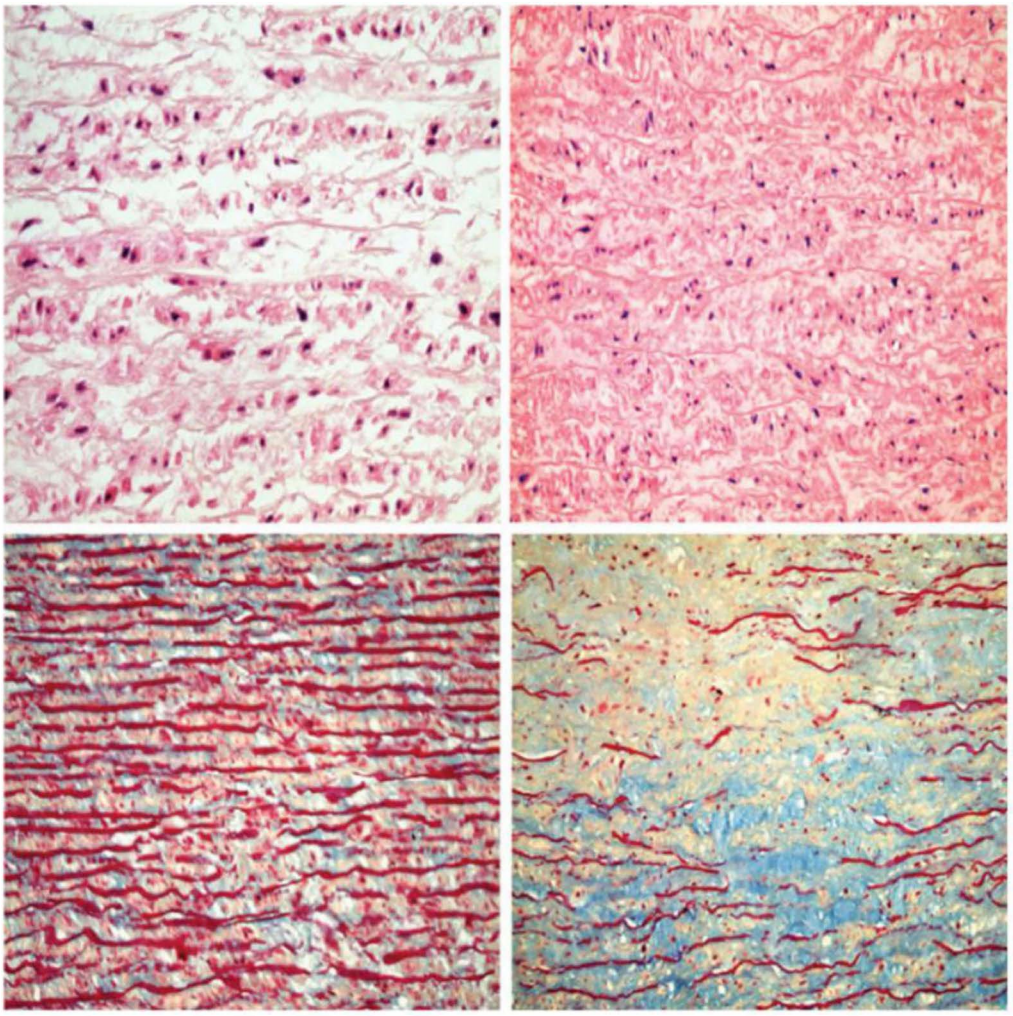

**FIGURE 39-5** Histology. Normal aorta stained with hematoxylin and eosin (H&E) × 120 (*upper left*) showing uniform distribution of elastin layers and fibromyocytes between them and Alcian blue/fuchsin/picric acid stain × 120 (*lower left*) with elastin stained red, fibromyocytes pale khaki-colored, and connective tissue pale gray–blue. Erdheim disease of the aorta stained with H&E × 120 (*upper right*) shows irregular distribution of fibromyocytes with irregularity and loss of elastic lamellae. In the lower right, Alcian blue/fuchsin/picric acid stain × 120 shows disruption and loss of elastic lamellae (*red*) and a hyperabundance of acidic mucin (*green–blue*).

hypertension, and TAAD. Aortic root dilation is present in approximately 40 percent of Turner syndrome patients. Another rare genetic disorder that occasionally predisposes to aortic aneurysms is Noonan syndrome, an autosomal dominant condition.

***Bicuspid Aortic Valve Disease.*** BAV is the most common congenital heart malformation, with a population prevalence of 1 to 2 percent. It is not clear whether BAVs are heritable, but groups have shown that there is a high incidence of familial clustering that is compatible with an autosomal dominant inheritance pattern with reduced penetrance.[34–36] Familial aggregation studies have indicated that 9.1 percent of persons with BAV have a first-degree relative with BAV, with males and females equally affected.[36] The clinical consequences of BAV disease focus on either valvular (stenosis, insufficiency, or infection) or vascular (dilation or dissection) complications. Sabet and coworkers[37] performed a large pathologic review and revealed that BAV disease results in a stenotic lesion in three-quarters of patients, insufficiency in 15 percent, and a mixed lesion in 10 percent. The vascular complications of BAV disease are less well understood, but the presence of BAV is an independent risk factor for progressive aortic dilation, aneurysm formation, and dissection.[38] In fact, BAV disease carries a 9- to 18-fold higher incidence of ascending aortic dilation.[39,40] The cause of this association initially was attributed to "poststenotic dilation," with high-velocity turbulent flow distal to a stenosis leading to downstream dila-

tion. However, advances in molecular biology have offered new insights that implicate intrinsic abnormalities of the aortic wall as being responsible for the pathologic development of aortic dilation. Embryologically, the aortic valvular cusps and ascending arterial media both arise from common neural crest cells during development. Apoptosis of those neural crest derivatives, specifically premature vascular smooth muscle cell apoptosis within the aortic media, is present in ascending aortic aneurysms of BAV carriers.[41,42] In addition, fibrillin-1 deficiency in the aortic media of BAV patients has been implicated in triggering matrix metalloproteinase (MMP) production, leading to matrix disruption and thus aortic dilation (Fig. 39-6).[43] The cause of BAV is unknown, but it is associated with accelerated degeneration of the aortic media, indicating that BAV disease is an ongoing pathologic process, not a discrete developmental defect.[44]

## Chronic Aortic Dissection

Both Stanford type A and type B chronic aortic dissections tend to dilate over time. The natural history starts with a vulnerable aortic wall at baseline, which is stressed with the tearing of the intimal flap, leaving the structural integrity of the aorta destabilized to only the weakened outer wall of the false lumen. Consequently, those with chronic aortic dissection are at high risk for aneurysm formation. Debakey and colleagues found that aneurysms developed in 46 percent of patients with uncontrolled hypertension but in only 17 percent with controlled hypertension.[45] Recently, Griepp and coworkers found that after repair of acute type A dissections, the growth of the distal aorta averaged 0.85 mm a year for the aortic arch and 1.24 mm a year for the descending thoracic aorta.[46]

## Infection

### MYCOTIC ANEURYSMS

Osler[47] adopted the term *mycotic* to denote aneurysms originating on the basis of infection.[48] Mycotic aneurysms of the thoracic aorta are rare but can be fatal if they are not diagnosed early. Bacterial seeding of the aortic wall can occur by hematogenous spread to the intima or the vasa vasorum, lymphatic spread, or direct extension from an adjacent infected focus. The thin endothelial intimal lining of the aorta is generally highly resistant to infection, but disruption of this barrier by atherosclerosis reduces resistance to infection.[49] Epidemiologically, this disease, which traditionally has been due to endocarditis, now has an increased tendency to afflict the elderly, possibly as a result of an atherosclerotic load facilitating infection. Aneurysms are usually saccular and well localized, with *Staphylococcus aureus* and *Salmonella* species being the predominant organisms. Surgery with complete excision and debridement of infected tissue with in-line aortic reconstruction is the definitive treatment. Lifelong prophylactic antibiotic therapy may be advisable to prevent recurrences unless there is a clearly identifiable and treatable source of infection.

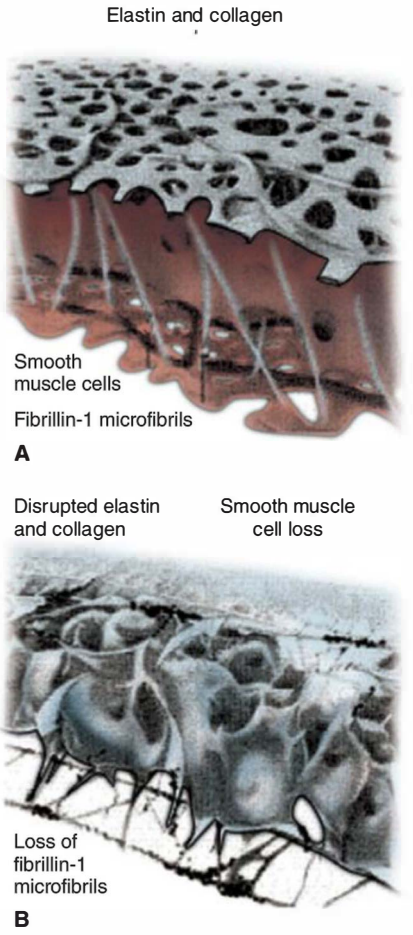

**FIGURE 39-6** The elastic laminae of the aortic media provide structural support and elasticity to the aorta. In normal tricuspid valve patients (**A**), fibrillin-1 microfibrils tether smooth muscle cells to adjacent elastin and collagen matrix components. In patients with BAV (**B**), deficient microfibrillar elements result in smooth muscle cell detachment, matrix metalloproteinase release, matrix disruption, cell death, and a loss of structural support and elasticity. (Reproduced, with permission, from Fedak PW, Verma S, David TE, et al. Clinical and pathophysiological implications of a bicuspid aortic valve. *Circulation* 2002;106(8):900–904.)

### SYPHILITIC ANEURYSMS

Syphilis was once perhaps the most common cause of ascending aortic aneurysms, but in an era of aggressive antibiotic treatment, such luetic aneurysms are seen rarely in medical centers.[50] Syphilitic aortitis is a chronic mesarteritis and periarteritis of the aorta, with patchy destruction and scarring of musculoelastic medial tissue and replacement by vascularized connective tissue.[48] The complications of

aortitis develop 10 to 20 years after onset of disease in most cases, with the most common manifestation being a localized saccular aneurysm in the ascending aorta.[51]

## Inflammatory Aneurysms

Walker and colleagues[52] were the first to define the term *inflammatory aneurysm*. Typical histologic examination shows signs of chronic inflammation in the adventitia with a marked lymphoplasmacytic cell infiltrate and granulation or proliferation of fibrous tissue. Three inflammatory arteritides affect the ascending and arch of the aorta with aneurysmal disease: Takayasu arteritis, Behçet disease, and giant cell arteritis (GCA).

### TAKAYASU ARTERITIS

Takayasu arteritis is a nonspecific inflammatory disease of unknown etiology that mainly involves the medial layer in the elastic arteries such as the pulmonary artery, the subclavian artery, and abdominal branches of the aorta.[53] The inflammatory process results in a predominantly chronic arterial occlusive lesion of the main branches of the aortic arch but occasionally results in arterial aneurysmal formation, following a cyclic course.[54] Histologically, thickening of the intima is the normal occurrence, resulting in stenosis and occlusion; however, degeneration of the elastic tissue with proliferation of the connective tissue mainly in the medial layer of the arteries may result in dilatation of the artery and aneurysm formation.[54]

### BEHÇET DISEASE

Behçet disease is a multisystemic disorder characterized by recurrent urogenital ulcers, ocular manifestations, and skin lesions, with cardiovascular involvement appearing in only 7 to 29 percent of patients.[55] However, the leading cause of death in patients with Behçet disease is rupture of a large aortic or arterial aneurysm.[56] Venous lesions are the norm, with arterial manifestations accounting for only 12 percent of vascular complications in patients with Behçet disease. The arterial lesion, which develops in the aorta and the pulmonary artery as well as in their major branches, is an aneurysm in 65 percent of patients and an occlusion in 35 percent.[55] At histologic analysis, aortitis is seen in both the active and scar stages. Active aortitis leads to the destruction of the media and fibrosis, predisposing the patient to saccular aneurysms.[57] Perforation of the arterial wall caused by obliterative endarteritis of the vasa vasorum may result in aneurysm formation or rupture.[58]

### GIANT CELL ARTERITIS

GCA, also known as temporal arteritis, cranial arteritis, granulomatous arteritis, and Horton disease, is a chronic systemic vasculitis of unknown etiology that affects medium-size and large arteries.[59–61] It has been reported that as many as 15 percent of patients with temporal arteritis may have angiographic evidence of aortic involvement[62] and that patients with GCA are 17.3 times more likely to develop a thoracic aortic aneurysm than is the general population.[63] Typical histopathologic findings are disruption of the internal elastic lamina and an inflammatory cellular infiltrate with giant cells.[61]

## Complications of Ascending Aortic Dilation

Dilation of the ascending aorta is currently the most common cause of isolated aortic valvular regurgitation.[64] A normal valve becomes incompetent as a result of the passive stretching of its leaflets and commissures caused by dilation of the sinotubular ridge, the ascending aorta, or the sinuses, although the aortic annulus often remains normal in size in the non-Marfan population.

# CLINICAL FEATURES

The decision to recommend surgical therapy is based on the clinical assessment that the potential for complications during observation and the associated consequences are more significant than the morbidity and mortality of surgical repair. This clinical decision must rely on current knowledge of the natural history of ascending and arch aneurysms.

## Natural History

Unlike the natural history of untreated abdominal aortic aneurysms, the natural history of thoracic aortic aneurysms is ill defined, mainly because of the asymptomatic course of the disease until dissection, rupture, or the appearance of symptoms. The majority of the published information details the natural history of descending thoracic aneurysms, with substantially less information available for ascending or arch aneurysms. With that caveat, there is comprehensive information available for ascending and arch aneurysms related to MFS, but such data are lacking for other pathologies. It is appreciated that the size and etiology of the aneurysm contribute to the natural history of thoracic aortic aneurysms, which often concludes with patient death because of rupture or dissection.

### SIZE

According to Laplace law,

$$T = (P \times R)/M$$

where $T$ is the tension in the walls, $P$ is the pressure difference across the wall, $R$ is the radius of the cylinder, and $M$ is the thickness of the wall; the combination of an enlarging radius and a thinning wall leads to increased wall tension. This represents the onset of a positive feedback cycle that

results in progressive aortic dilation and culminates in rupture or dissection. In all reliable contemporary natural history studies, an ascending aortic diameter of 6 cm emerges as the mean or the median diameter quite consistently.[65] Coady and associates found that a diameter of 6 cm is the "hinge point" beyond which there is a 30 percent increase in the probability of rupture.[66] The 5-year survival rate for patients with ascending aortic aneurysms ranged from 36 to 61 percent in the earlier days[67] and reached 59 to 77 percent in the modern era[68] for aneurysms equal to or greater than 6 cm and less than 6 cm, respectively. Regarding aneurysm growth rates, Hirose and coauthors noted that the growth rate of aneurysms was greater in the arch (0.56 cm/year) than in the descending thoracic (0.42 cm/year) or the abdominal aorta (0.28 cm/year).[69] A more recent review of the Yale database[70] reported an annual growth rate of 0.07 cm for aneurysms in the ascending aorta or aortic arch and found that increasing size is associated more strongly with an increased risk of rupture than with an increased risk of dissection. In addition, the risk of rupture with time as a function of initial aneurysm size is 11 times worse with an aortic size of 5.0 to 5.9 cm and nearly 27 times worse with a size of 6.0 cm or greater when each is compared with aneurysms less than 4.0 cm.

### ETIOLOGY

In addition to aneurysm size, the etiology of the aneurysm has a profound impact on rupture, dissection, and death. The most common cardiovascular complication in patients with MFS is progressive aortic root enlargement that initially occurs at the sinuses of Valsalva. An ascending aortic aneurysm can precipitate acute type A dissection, aortic rupture, aortic regurgitation (AR), or all three, and these complications were the primary cause of death before the advent of successful preventive therapies.[2] Currently, aortic dissection is the major cause of premature morbidity and mortality in patients with MFS. In a study by Murdoch and associates,[71] that looked at causes of death in MFS patients, cardiovascular manifestations accounted for 93 percent of the deaths (52 of 56), with aortic root complications (dilation, dissection, and regurgitation) accounting for 80 percent of those deaths with an average age at death of 32 years. This was similar to the findings of Marsalese and coworkers, in which 87 percent of the known causes of death were attributable to the cardiovascular system and 61 percent were the result of aortic dissection, rupture, or sudden cardiac death with a mean age at death of 35 years.[72]

BAV is also an independent risk factor for progressive aortic dilation, aneurysm formation, and dissection.[73] Dore and associates[74] evaluated 50 adults with BAV with transthoracic echocardiography (TTE) and found that progressive dilation occurred at all levels (from the basal attachment of the leaflets to 1 cm beyond the STJ), ranging from 0.3 mm/year at the basal attachment within the left ventricular outflow tract to 1.0 mm/year 1 cm beyond the STJ. These rates of dilation are greater than the reported rate of 0.8 mm/decade in the normal population. In fact, BAV disease carries a 9-to-18-fold higher incidence of ascending aortic dilation.[75,76] Furthermore, valve replacement of BAV for either aortic insufficiency or stenosis does not eliminate the risk of aortic complications. After aortic valve replacement, BAV patients, when compared with tricuspid aortic valve patients, have progressive dilation of the proximal ascending aorta[77] and have a greater incidence of sudden death and aortic events.[78] Thus, the influence of BAV disease on the ascending aorta is a reality; surgeons should consider valve pathology when making decisions about ascending aortic replacement.

The natural history of LDS, resulting from a spectrum of mutations in *TGFBR1* or *TGFBR2*, differs considerably from other connective tissue disorders with the average age at the first cardiovascular event much lower than that for patients with untreated MFS or vascular EDS. In a cohort of 90 patients,[32] the median survival was 37.0 years, with 27 deaths during the study period with the mean age of death being 26.0 years (range: 0.5–47.0), and the mean age at vascular surgery—most often for ascending aortic aneurysm or dissection—was 19.8 years (range: 1.2–46.0). Twenty-nine patients (32 percent of the cohort) died before the age of 19 as a result of a vascular dissection or rupture, suggesting that LDS is an aggressive connective tissue disorder with a worse cardiovascular risk profile than classic MFS, including aortic dissection at a young age and at small dimensions.

## DIAGNOSTIC MODALITIES

### Typical Clinical Presentations

#### SYMPTOMS

Most patients with thoracic aortic aneurysms are asymptomatic at the time of presentation, and aneurysms of the ascending aorta usually are detected as incidental findings during testing for other disorders. Examples include widening of the mediastinum or prominence of the aortic knob on routine chest radiography and aortic enlargement on echocardiography, thoracic computed tomography (CT), or magnetic resonance imaging (MRI). In contrast, aneurysms of the aortic arch, because of their anatomic location and the space-occupying nature of the aneurysm, may impinge on important mediastinal structures and are therefore symptomatic more often than aneurysms of the ascending or descending thoracic aorta.[24] Hoarseness results from stretching of the left recurrent laryngeal nerve, stridor from compression of the trachea, dysphagia from impingement on the lumen of the esophagus, dyspnea from compression of the lung, and plethora and edema from compression of the superior vena cava (SVC).[79] Aneurysms of the ascending aorta associated with dilation of the aortic valve annulus may present with signs and symptoms of AR. In addition, chest or back pain may indicate acute expansion or leakage of the aneurysm in which the location of discomfort roughly correlates with the involved aortic

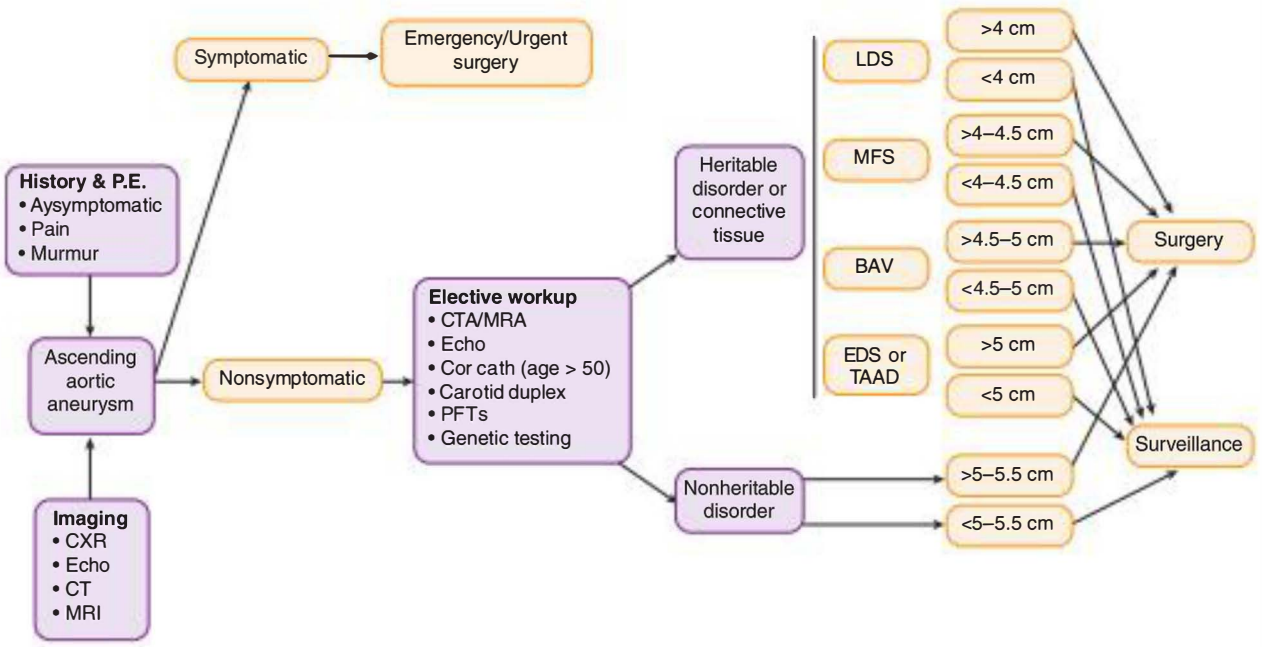

**FIGURE 39-7** Decision-making flowchart: ascending aortic aneurysm.

segment. Precordial pain is associated with involvement of the ascending aorta; radiation to the neck and jaw often accompanies aortic arch involvement, whereas descending thoracic and thoracoabdominal aortic aneurysms tend to produce interscapular and low back pain, respectively. In contrast, the clinical features of aortic dissection are the acute onset of chest and/or back pain of a blunt, severe, and sometimes radiating and migrating nature.[80] Symptoms attributable to the aneurysm are cause for concern and consideration for early surgical intervention. Patients with rupture of an ascending or arch aneurysm often present in extremis (see Figs. 39-7 and 39-8).

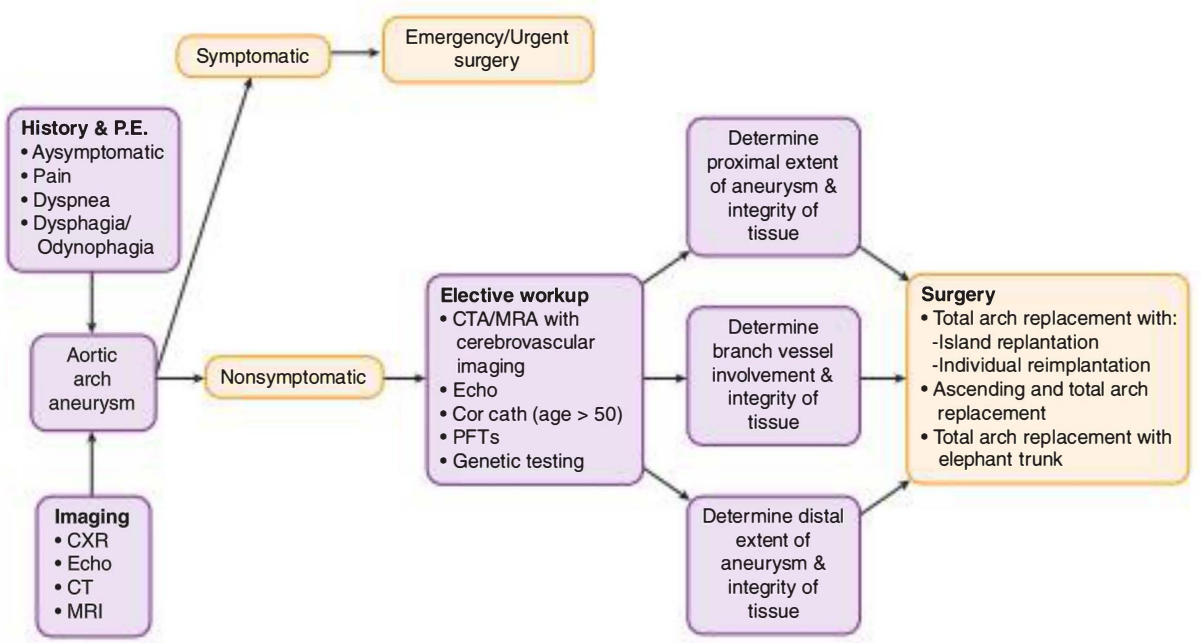

**FIGURE 39-8** Decision-making flowchart: aortic arch aneurysm.

### SIGNS

The physical examination is often normal in a patient without rupture of an ascending or arch aneurysm, with the rare exception of a large aneurysm that is palpated in the suprasternal notch. Other physical findings may include venous distention secondary to superior vena caval or innominate vein obstruction. Aneurysms of the ascending aorta associated with dilation of the aortic valve annulus may present with signs of AR (i.e., widened pulse pressure, decrescendo diastolic murmur, bisferiens pulse, "pistol-shot sound," Duroziez sign, and Quincke pulse). A thorough vascular examination should be carried out to identify concomitant peripheral vascular disease (abdominal aortic aneurysms are present in 10–20 percent of patients with atherosclerotic involvement of an ascending aortic aneurysm).[81,82] The physical examination also should focus on identifying marfanoid features (Fig. 39-4) as well as phenotypic features of LDS (i.e., blue sclerae, hypotelorism, bifid uvula, malar flattening, retrognathia, camptodactyly, arachnodactyly, and translucency of the skin with visible veins and distended scars[32]).

## Hallmark Primary Laboratory Abnormalities

There are no primary laboratory abnormalities associated with aortic aneurysmal disease.

## Recommended Diagnostic Studies

The diagnosis of aortic aneurysms has been revolutionized by developments in cross-sectional imaging. Traditionally, these aneurysms were investigated by contrast angiography, but the last two decades have seen considerable developments in the diagnosis of aortic disease by echocardiography, CT, and MRI. These developments have led to a complete change in the way in which aortic disease is evaluated and have contributed to an improvement in treatment outcomes.[83]

When a thoracic aortic aneurysm is detected, it is typically not possible to determine the rate of growth; therefore, if the aneurysm does not meet the criteria for surgical intervention, it is appropriate to obtain a repeat imaging study 6 months after the initial study. If the aneurysm is unchanged in size, it is reasonable to obtain an imaging study on an annual basis in most cases. However, if there is a significant increase in aortic size from one study to the next but surgical intervention is still not indicated, the interval between studies should be decreased to 3 or 6 months. For surveillance to be useful, serial imaging studies should be performed in the same center with the same technique so that direct comparisons can be made between comparable images.[50]

### CHEST ROENTGENOGRAPHY

The abnormality of a thoracic aneurysm may be detected on chest radiographs, with the most common finding being widening of the superior mediastinum. Other findings include displacement and compression of the mediastinal contents, such as the trachea and esophagus, and curvilinear calcification in the aneurysmal wall (Fig. 39-9).[84] However, aneurysms that involve the ascending aorta and the aortic arch sometimes cannot be differentiated from tumors or other masses in the mediastinum.[85]

### ECHOCARDIOGRAPHY

Both TTE and transesophageal echocardiography (TEE) play an important role in aortic imaging. Echocardiography is widely available, noninvasive (TTE) or minimally invasive (TEE), and relatively inexpensive. TTE can visualize the aortic root and ascending aorta accurately and is very suitable for evaluating the size of moderate aneurysms and assessing cardiac complications such as AR, impaired left ventricular function, and hemopericardium (Fig. 39-10). It is less than ideal for showing the full extent of the aortic arch and evaluating the origins of head and neck vessels. In contrast, TEE with the current multiplanar transducers has few blind areas (i.e., posterior to the trachea) that limit evaluation. Most important, because of its bedside applicability, TEE is the imaging modality of choice for the diagnosis and exclusion of ascending aortic dissection in an unstable patient, with a European multicenter study reporting a diagnostic sensitivity of 99 percent and a specificity of 98 percent.[86] Combined with color flow imaging, TEE allows not only the identification of the intimal flap with the true and the false lumen and identification of the entry and reentry tears but also the detection of associated complications such as AR, pericardial and pleural effusions, coronary involvement, and thrombosis in the false lumen. Today, in most centers, patients with proximal aortic dissection diagnosed by TEE who are surgical candidates are taken directly to the operating room, saving valuable time. In addition, intraoperative application of TEE allows continuous monitoring of the surgical procedure without disturbing the sterile field, in contrast to epicardial echocardiography.

### COMPUTED TOMOGRAPHY AND COMPUTED TOMOGRAPHY ANGIOGRAPHY

Because of its speed and wide availability, CT and computed tomographic angiography (CTA) are currently the most common diagnostic imaging methods for studying the aorta. With the advent of multidetector-row scanners, CT can provide the excellent spatial resolution necessary to image the aorta accurately with reasonable doses of iodinated contrast medium with a short acquisition time.[87] Limitations on contrast use because of renal insufficiency or a history of allergy usually can be dealt with, particularly when there is an urgent need to make a definitive diagnosis. CTA combines a rapid bolus intravenous injection using a pressure injector with a timed breath hold and spiral CT acquisition during peak arterial opacification. Curved planar reformations and three-dimensional (3-D) reformations using maximum-intensity projection (MIP) and shaded surface display (SSD) after segmentation and editing of bony and other unwanted

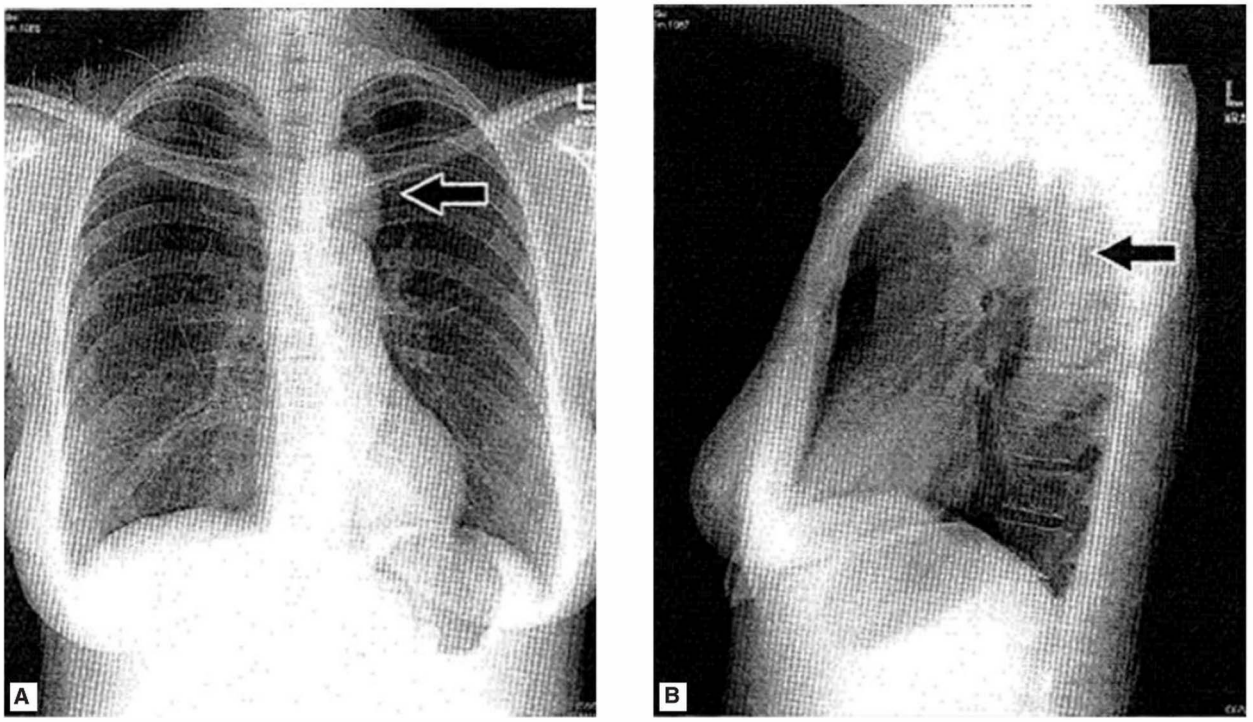

**FIGURE 39-9** Chest roentgenography demonstrating an aortic arch aneurysm (*black arrow*) on both the anterior–posterior film and the lateral film.

structures provide excellent visualization of the aorta and its branch vessels (Figs. 39-11 and 39-12).[88] CTA (axial images) has the advantage of demonstrating aortic wall thickening, calcification, and luminal thrombus, thus displaying the true axial extent of the aneurysm, as the aortography or 3-D MIP and SSD images display only the enhancing lumen of the vessel. In addition, these wall parameters are important in establishing the etiology of the aneurysm and in decision making for further management. However, it should be noted that measurement based purely on the basis of axial images, which may not be orthogonal, can be misleading. Tortuosity of the aorta can lead to a false estimation of aneurysm size; therefore, 3-D SSD reconstruction has facilitated assessment of aneurysm size and extent significantly.

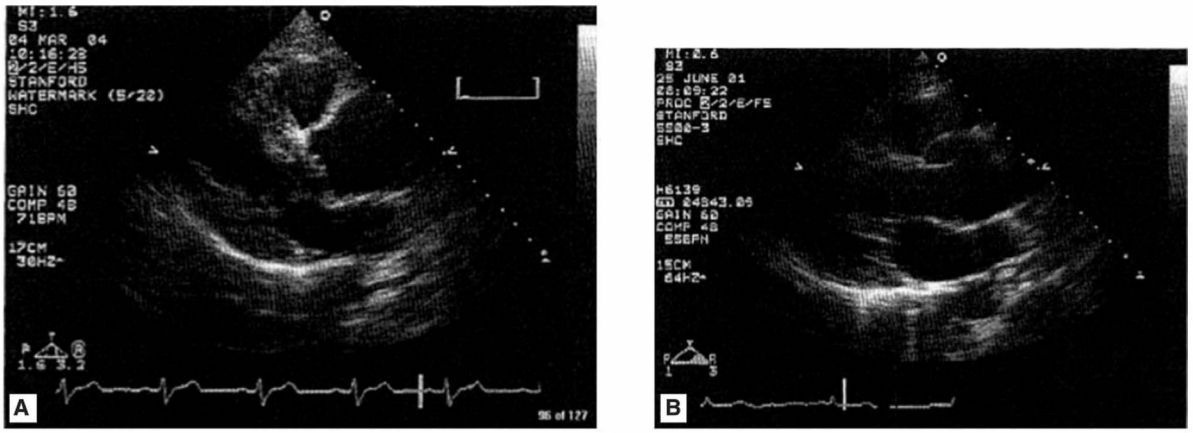

**FIGURE 39-10** Echocardiography. **A**. Long-axis view of a patient with a bicuspid aortic valve and an ascending aortic aneurysm. Note that the ascending aneurysm starts at the level of the sinotubular junction without dilation of the sinuses. **B**. In contrast, note the long-axis view of a Marfan disease patient with dilation of both the sinuses and the ascending aorta.

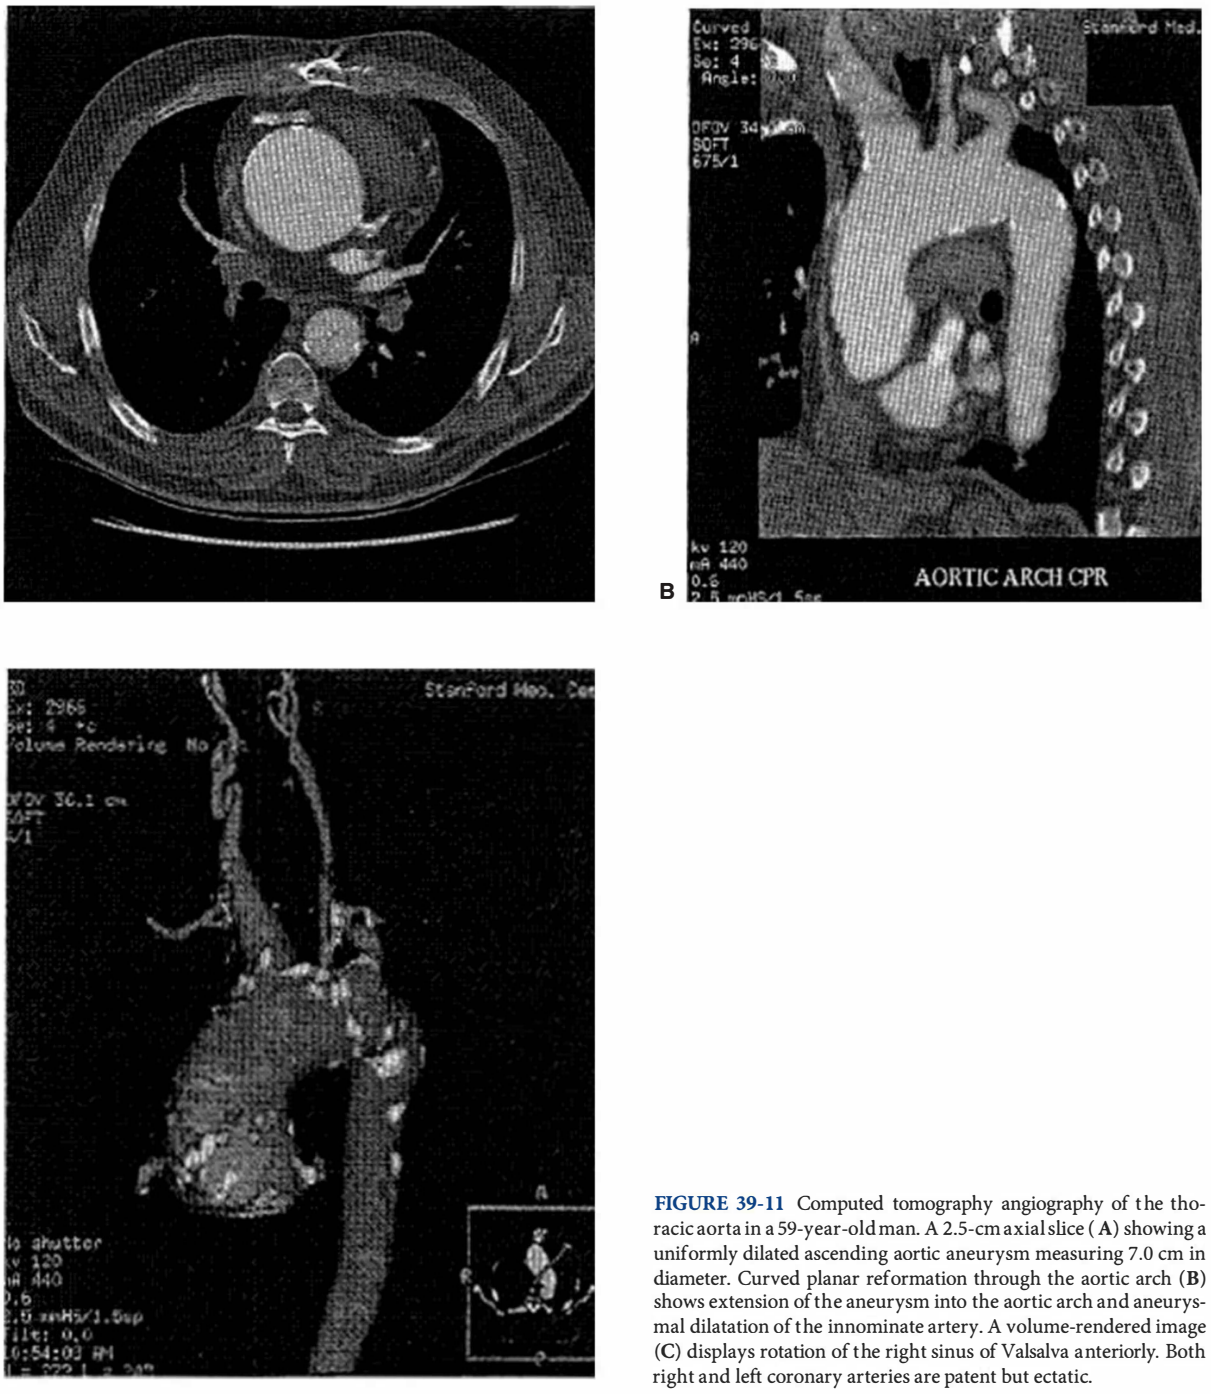

**FIGURE 39-11** Computed tomography angiography of the thoracic aorta in a 59-year-old man. A 2.5-cm axial slice (**A**) showing a uniformly dilated ascending aortic aneurysm measuring 7.0 cm in diameter. Curved planar reformation through the aortic arch (**B**) shows extension of the aneurysm into the aortic arch and aneurysmal dilatation of the innominate artery. A volume-rendered image (**C**) displays rotation of the right sinus of Valsalva anteriorly. Both right and left coronary arteries are patent but ectatic.

CTA is the imaging study of choice in a suspected leaking aneurysm, in which rapid evaluation is imperative. In elective ascending and arch aneurysm repair, CTA is able to display the origins of aortic branches and their relation to the aneurysm, the proximal and distal extent of the aneurysm, and the adjacent thoracic structures, all of which are critical to operative planning. Currently, 64-bit scanners also are capable of imaging coronary arteries, eliminating the necessity for selective catheter injection for coronary assessment.

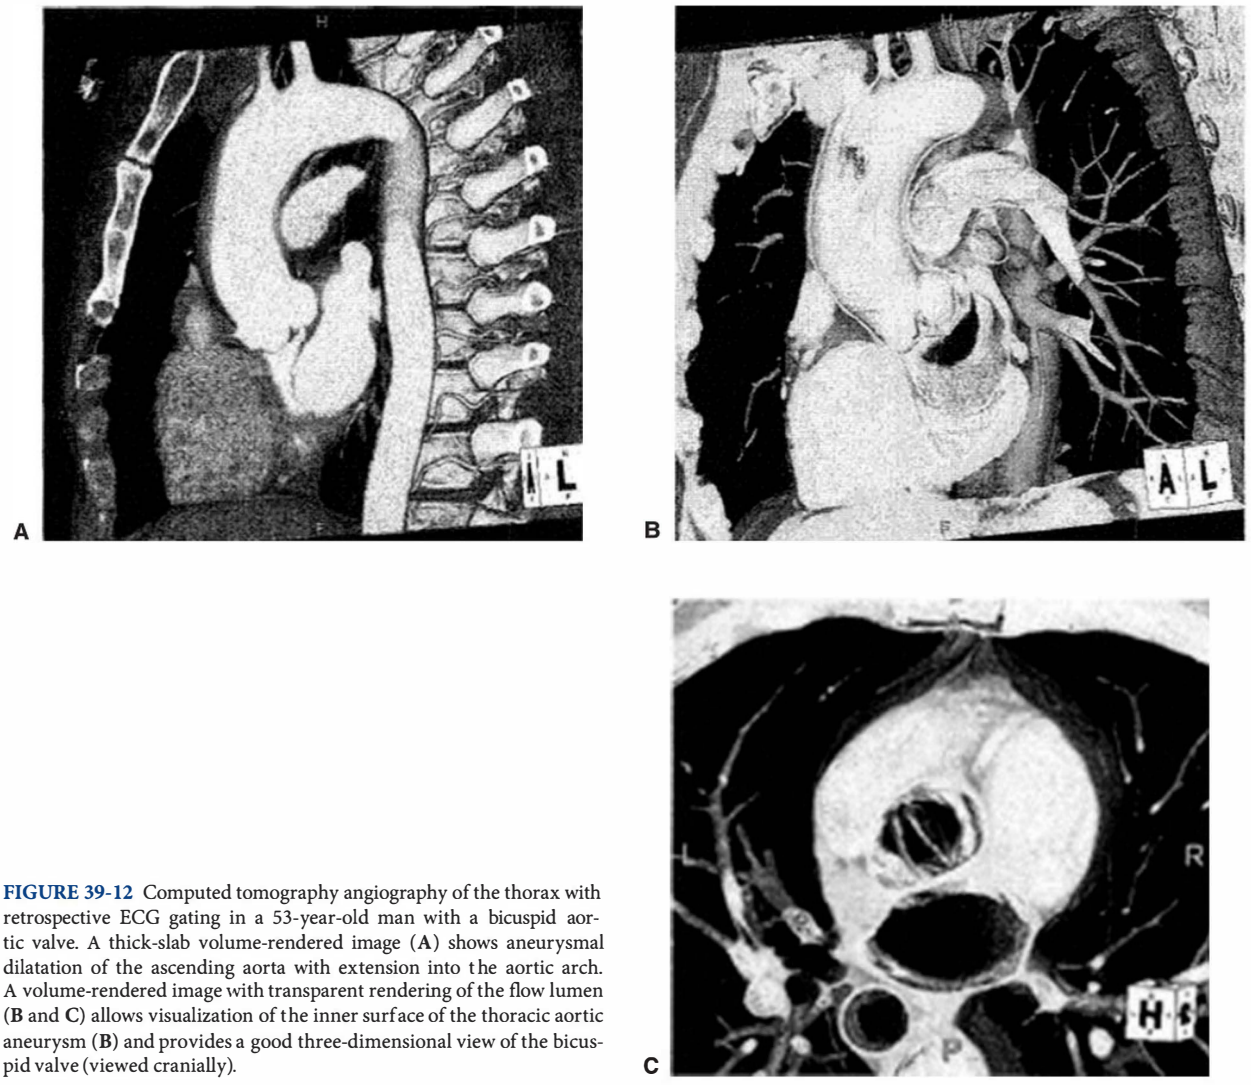

**FIGURE 39-12** Computed tomography angiography of the thorax with retrospective ECG gating in a 53-year-old man with a bicuspid aortic valve. A thick-slab volume-rendered image (**A**) shows aneurysmal dilatation of the ascending aorta with extension into the aortic arch. A volume-rendered image with transparent rendering of the flow lumen (**B** and **C**) allows visualization of the inner surface of the thoracic aortic aneurysm (**B**) and provides a good three-dimensional view of the bicuspid valve (viewed cranially).

### MAGNETIC RESONANCE IMAGING AND MAGNETIC RESONANCE ANGIOGRAPHY

MRI is emerging as the premier imaging method for the diagnosis of diseases of the thoracic aorta in stable patients. MRI provides visualization in the sagittal and coronal planes and eliminates the need for noniodinated contrast and radiation exposure. Magnetic resonance angiography (MRA) of the thoracic aorta usually requires a combination of several available MRI methods, each of which has certain advantages and contributes to the diagnostic versatility of the technique. Contrast-enhanced MRA (CE-MRA) is the most widely used MRA method because it is rapid and robust, providing projection images of the aorta similar to those provided by conventional invasive angiography. Black-blood MRI permits assessment of the vessel wall by saturating the signal from the lumen. Phase-contrast imaging provides functional information about the flow. Gradient-echo cine images can demonstrate AR in the presence of disease of the ascending aorta. The field continues to develop, and many new MRA methods promise further improvements in acquisition time and resolution.[89] However, MRI/MRA is less readily available and has limited utilization in acute aortic problems because of limited applicability to ventilated and invasively monitored patients. Indwelling pacemaker wires also frequently prevent its use.

## MEDICAL TREATMENT

The medical therapies available to slow the growth of thoracic aortic aneurysms and reduce their risk of dissection or rupture are quite limited, and most studies have focused

on Marfanoid patients. Whether these benefits truly can be extrapolated to the non-Marfan population with thoracic aneurysms is unknown.[50] Some early experimental evidence suggests that oxidative stress may play a role in the pathogenesis of atherosclerotic thoracic aortic aneurysms and that perhaps therapy with statins, MMP inhibitors, and angiotensin II receptor blockers may have a protective effect.[90,91]

## Marfan's Syndrome

Studies addressing the efficacy of β-blockade in MFS patients have concluded that such therapy is successful in a subset of individuals.[92,93] Overall, medicated patients showed slower aortic root growth (defined as absolute growth rate or growth rate adjusted for age and body size), fewer cardiovascular endpoints (defined as AR, dissection surgery, congestive heart failure, or death), and an improved survival rate.[2] It is important to note that even though abnormal aortic growth was slowed significantly in medicated patients, therapy did not prevent aortic dilation[94–96] or the need for surgical correction. Currently, it is recommended that all patients with MFS be considered for β-adrenergic blockade to reduce inotropy and chronotropy and thereby reduce both acute and chronic hemodynamic stress on the aortic root. Treatment begins with a low dose, which is titrated to keep the heart rate below 70 in a resting state and below 100 after submaximal exercise. Contraindications to β-adrenergic blockade include severe diabetes, Raynaud phenomenon, and bronchospasm. In the setting of β-blocker intolerance, a trial with a calcium channel blocker is indicated on the basis of a small trial that suggested its efficacy in protecting the MFS aorta.[93] Encouraging results in the Marfan rat model with angiotensin-converting enzyme (ACE) inhibitors may warrant a clinical trial.[97,98]

Exercise restriction represents a second approach to reducing hemodynamic stress in MFS patients.[99] Individuals with MFS are encouraged to remain active; aerobic exercise should be performed in moderation, but contact sports should be avoided. Most important, they should avoid isometric exercises, especially weight lifting, because of the marked elevation in blood pressure that occurs during sustained maximal muscle contraction.[2]

## Bicuspid Aortic Valve

The benefit of β-blockers in preventing aortic dilation in BAV disease is not clear; however, hypertension should be monitored and controlled carefully. The role of MMP inhibitors and gene or protein therapy in augmenting deficient extracellular matrix components in the bicuspid aorta is an exciting prospect that warrants further investigation.[100]

## Loeys–Dietz Syndrome

The mechanism by which mutations in the TGF-receptor cause the multisystem manifestations of LDS is complex and poorly understood. TGF-antagonists have the ability to alleviate or eliminate many manifestations, including aortic aneurysmsin mouse models of MFS.[101] Although the application of this approach to LDS may prove beneficial, caution is warranted pending validation in genetically defined animal models.[32]

# SURGICAL TREATMENT

The optimal timing of surgical repair of thoracic aortic aneurysms is somewhat uncertain in light of the limited data on their natural history.[50] The major objectives of surgical treatment are to alleviate symptoms related to the aortic disease, reduce the frequency of complications associated with the specific aortic disease, and, in the case of aortic aneurysm, prevent death from rupture. Extensive aortic disease may require staged operative procedures.[102]

## Indications for Operation

### SYMPTOMS

Symptomatic patients with ascending or arch aneurysms should be evaluated urgently for surgical repair. Patients presenting with rupture should be operated on urgently, since these conditions are almost uniformly fatal without prompt surgical intervention.

### SIZE AND GROWTH RATE

Current recommendations for elective resection of the ascending aorta are based on the fact that the mean diameter of the aorta at the time of dissection or rupture is around 6 cm, but this actually means that half of these patients have experienced a highly lethal complication by the time a diameter of 6 cm is reached.[103] Therefore, with the markedly reduced operative risk today, the authors, as do others,[104,105] recommend ascending aortic operations in nonheritable connective tissue disorder patients when the ascending aortic aneurysm diameter ranges from 5 to 5.5 cm. For patients who have diameters less than 5 cm and are being monitored with serial imaging, an indication for surgical intervention would be a 10 percent increase in size over a 6- to 12-month time course. In addition, since the majority of ascending aortic aneurysms are discovered in the course of evaluation for aortic insufficiency, progressive aortic valvular regurgitation is another common indication for operation.

### INFLUENCE OF ETIOLOGY

Patients with a heritable disorder of connective tissue such as MFS, EDS, LDS, BAV, or TAAD who have an ascending or arch aneurysm require earlier surgical intervention than do patients with nonheritable aortic disease. The traditional threshold that prompts the consideration of prophylactic aortic root replacement in patients with MFS has

been predicated on aortic size, and replacement is recommended when the diameter reaches 5.0 cm.[106,107] The association between increased aneurysm diameter and the risk for dissection or rupture has been established clearly, and aneurysm size greater than 6 cm portends a four-fold increase in the cumulative risk of aortic rupture or dissection in patients with MFS.[107] Some patients with MFS experience acute dissections when the aortic diameter is less than 5.0 cm.[108] In patients with LDS, aortic dissection often occurs in childhood and in aortas with diameters well under 5 cm.[32] Therefore, for heritable disorders of connective tissue, surgical intervention for the ascending aorta should be considered at a diameter approaching 4 cm for LDS patients, 4 to 4.5 cm for MFS patients, 4.5 to 5 cm for BAV patients, and 5 cm for EDS or TAAD patients. In addition, young children with LDS should undergo surgical intervention when the maximal dimension of the ascending aorta exceeds the 99th percentile and the diameter of the aortic annulus exceeds 1.8 cm.[32] For patients with ascending aortic aneurysms below these values, surveillance is warranted. Factors that prompt a recommendation for surgery when the aorta is less than 5.0 cm include rapid growth of the aortic diameter (more than 1 cm/year), a family history of premature aortic dissection (dissection less than 5.0 cm), and the presence of moderate or severe AR.[2]

## Choice of Operations

### ASCENDING AORTIC OPERATIONS

The surgical technique employed for treatment of an ascending aortic aneurysm varies with the underlying pathology and the quality of the aortic wall, the skill of the operating surgeon, the status of the aortic valve, and the age, expected survival, and general well-being of the patient.[23] The primary technical objectives of repair are surgical excision of all aneurysmal segments with graft replacement and restoration of function to the aortic valve.

Choosing the technique most appropriate for the patient and the pathology requires careful consideration of the factors that Ergin and associates[109] have outlined (Table 39-2). Among these factors are the following:

**TABLE 39-2: Factors Influencing the Choice of Ascending Aortic Operations**

| |
|---|
| Age and expected survival |
| Underlying pathology and quality of the aortic wall |
| Anatomic condition of aortic annulus, valve leaflets, sinuses, and sinotubular ridge |
| Condition of the distal aorta |
| Risk of anticoagulation |
| Presence of active annular infection |

Data from Ergin MA, Spielvogel D, Apaydin A, et al. Surgical treatment of the dilated ascending aorta: When and how? *Ann Thorac Surg* 1999;67(6): 1834–1839.

***Age and Expected Survival.*** In an older high-risk patient, separate valve and ascending aortic replacement may be the appropriate therapy if life expectancy is limited.[110] Reduction aortoplasty is less technically demanding than tube graft replacement of the ascending aorta, but the long-term results reveal a significant risk of recurrent dilation.[111,112]

***Underlying Pathology and Quality of the Aortic Wall.*** A weakened aortic wall in a patient with MFS or dissection will require complete excision of the dilated portion of the aorta and the root. The button modification of the Bentall procedure has proved in the authors' hands the most versatile and durable reconstruction.[113] Sparing the aortic valve in MFS patients is controversial,[114] although early data with 5-year follow-up is encouraging.

***Anatomic Condition of the Aortic Annulus, the Valve Leaflets, the Sinuses, and the Sinotubular Ridge.*** The anatomic condition of these important elements of aortic valvular integrity usually dictates whether the valve can be spared or whether a separate valve-ascending aortic replacement may be feasible. In the authors' experience, the ideal candidate for a valve-sparing root replacement is a patient with a normal valve and annulus in whom a dilated sinotubular ridge or dilated sinuses leads to aortic insufficiency. A separate valve and ascending aortic replacement that leaves behind thinned, dilated sinuses is a compromise that should be avoided in patients with a relatively long life expectancy.[115]

***Condition of the Distal Aorta.*** If the condition of the distal aorta mandates a future operation for associated distal arch or descending thoracic aortic aneurysm or dissection, a fail-safe initial repair at the root is of paramount importance. The presence of even modest degrees of AR may complicate an operation on the distal aorta substantially, and this frequently requires the utilization of hypothermic circulatory arrest. In these cases, the authors prefer a composite replacement rather than a valve-sparing procedure, except in the case of an absolutely normal valve with AR secondary to dilation of the STJ.

***The Risk of Anticoagulation.*** A young female desirous of child bearing presents a particularly challenging dilemma. A valve-sparing root repair or perhaps a pulmonary autograft may allow long-term durability. Reoperations on a biological CVG undoubtedly will incur more risk than will a simple aortic valve reoperation and should be avoided.

***Presence of Active Annular Infection.*** First and foremost, total excision of all infected tissue must be achieved. Annular and root reconstruction then can be accomplished with autologous materials, with the considerations for anticoagulation that were outlined above. Although low rates of reinfection may be achieved with conventional prostheses, repairs that avoid prosthetic material such as homografts and pulmonary autografts may be preferable.

### ARCH OPERATIONS

The specific technical aspects of aortic arch replacement depend on the location of the aneurysm within the arch and the extent of involvement of the contiguous ascending and descending thoracic aorta.[24] To replace the dilated arch with a prosthetic tube graft, the brachiocephalic vessels must be removed from the arch before its interposition. Traditionally, this involved removing and then reimplanting the brachiocephalic vessels en bloc during hypothermic circulatory arrest. However, many surgeons have adopted a newer surgical technique by using a multilimbed prosthetic arch graft to which each arch vessel is anastomosed individually in turn, thereby reducing the duration of hypothermic circulatory arrest; avoiding the proximal portion of the arch vessels, which is frequently diseased; and allowing inspection of all anastomoses for hemostasis.[50]

## Operative Technique

### PREOPERATIVE EVALUATION

Since myocardial infarction, respiratory failure, renal failure, and stroke are the principal causes of death and morbidity after operations on the thoracic aorta, preoperative assessment of the function of these organ systems is essential.[116]

### ANESTHETIC CONSIDERATIONS

Although the anesthetic management of patients undergoing aortic arch surgery includes practices common to most cardiac operations, there are conditions associated with the repair of aortic aneurysmal rupture that warrant special consideration. Anesthetic induction tends to blunt the sympathetically mediated compensatory responses of vasoconstriction and tachycardia that often are associated with acute thoracic aortic disruption. Therefore, acute cardiovascular collapse may result from conventional induction. To avoid this situation, endotracheal intubation and femoral vessel cannulation under local anesthesia with simultaneous institution of general anesthesia and CPB often are instituted in the setting of aneurysmal rupture.

***Standard Monitoring.*** After induction of anesthesia and intubation with a single-lumen endotracheal tube, venous access is obtained with a large-bore central line and several large-bore peripheral lines. For invasive arterial pressure monitoring and blood sampling, an arterial line is placed, but the location of placement is dependent on the operation that is being performed. If antegrade selective cerebral perfusion (ASCP) will be performed via the right axillary artery, the authors frequently monitor both left and right radial artery pressures. Pulmonary artery pressures, cardiac filling pressures, and cardiac output are measured by using a pulmonary artery catheter. Intraoperative TEE is used to estimate both ventricular filling and contractility, assess valvular function, allow selection of cannulation sites free of atherosclerotic disease, and confirm the appropriate advancement of the guidewire and venous cannula from the femoral vein into the SVC. Thermistor probes measure bladder, venous perfusate, and two tympanic temperatures. Five-lead electrocardiography and pulse oximetry are observed. Urine output is measured with a Foley catheter. Both invasive and noninvasive measures of cerebral oximetry also may be beneficial.

### PERFUSION

In the case of ascending aortic aneurysms, if an aneurysm does not involve the distal ascending aorta or the proximal aortic arch, these sites can be used for cannulation. If this is not possible, the axillary artery or innominate arteries may be used for arterial return from the pump-oxygenator. Femoral cannulation, especially in older patients with diffuse atheromatous disease, risks retrograde embolization to the brain as well as retrograde aortic dissection. Bicaval venous cannulation allows improved myocardial preservation as well as retrograde filling of the SVC as a final flush of particulate or gaseous material from the cerebral circulation before restoration of antegrade perfusion. In the case of arch aneurysms or if clamping of the ascending aorta is not possible, deep hypothermic circulatory arrest with additional cerebral protection is necessary.

### CEREBRAL PROTECTION

Because of its location, surgery of the aortic arch requires manipulation and exclusion of the cerebral circulation; therefore, cerebral protection is a primary concern and the utilization of optimal methods for the preservation of cerebral function is necessary to avoid ischemic or embolic brain injury. Over the past three decades, cerebral protection during arch procedures has evolved to avoid both the permanent and the transient neurologic dysfunction (TND) seen after aortic surgery. Initially, simple profound hypothermic circulatory arrest as described by Griepp and associates[17] seemed adequate, but it was associated with both focal and generalized neurologic injury with longer periods of arrest. Retrograde cerebral perfusion was popularized by Ueda and coworkers,[117] but TND was observed commonly with ischemic periods longer than 40 to 60 min. Selective antegrade cerebral perfusion and hypothermia as described by Kazui and colleagues[118] appears to provide cerebral protection for even longer ischemic periods (more than 40–60 min).

***Deep Hypothermia and Circulatory Arrest.*** The technique of deep hypothermia and circulatory arrest (DHCA) was described by Drew and associates in 1959.[119] Children undergoing surgery for Tetralogy of Fallot were cooled to 12°C (nasopharyngeal), allowing a circulatory arrest time of 1 h. The introduction of DHCA by Griepp and coworkers[17] as an operative tool more than 30 years ago still serves as the basis for the surgical treatment of complex thoracic aortic pathologies. This technique allows the performance of an open distal anastomosis and better visualization of the aortic

arch in a relatively bloodless field. The main disadvantages of DHCA include coagulopathy, increased CPB time, and renal and neurologic dysfunction.[120]

The vulnerability of the brain during circulatory arrest has been a great concern. Even at brain temperatures as low as 18°C, the safe arrest time is considered to be no longer than 30 to 40 min. An additional factor in the incidence of cerebral damage is the increasing age of these patients.[121] To protect the brain against ischemia, several different techniques are available, among which hypothermia is a standard, well-accepted application. To be able to establish the precise temperature of the brain, it is important to know which monitoring site is the most accurate for that purpose. The routinely used sites include esophageal, rectal, bladder, nasopharyngeal, pulmonary arterial, and skin temperatures. Several studies have compared the efficacy of the different monitoring sites in indicating the temperature of the brain, particularly in the dynamic phase of cooling and rewarming. Although core temperature sites, in particular bladder and esophageal temperature, may accurately reflect changes in body temperature during moderate hypothermia,[122,123] the accurate estimation of the optimal brain temperature site is still a matter of debate. The only available study in which brain temperature was measured directly during DHCA included patients undergoing surgical clipping of a cerebral aneurysm.[124] Routine monitoring sites, including tympanic temperatures, under- or overestimated brain temperature, with relatively large differences between individual patients. Although the effective time of arrest of cerebral perfusion has been shortened substantially by the application of antegrade low-flow cold blood cerebral perfusion, it is still important to assess cerebral temperature as accurately as possible. In the authors' practice at Stanford, this includes the measurement of bladder temperature, venous perfusate temperature, and two tympanic temperatures.

Since hypothermia is applied for brain protection because it diminishes cerebral oxygen consumption ($CMRO_2$), electroencephalography (EEG) monitoring has been advocated to assess uniform cooling and the degree of depression of the electrical signaling obtained during cooling. However, the EEG records only the postsynaptic potentials of cortical neurons, not the metabolic status of basal structures. During cooling, the EEG becomes isoelectric between 20°C and 18°C, but consistency of variation during hypothermia is unproven. The association between intraoperative EEG changes and postoperative neurologic deficits is weak. Still, EEG is used to determine electrical silence before DHCA and assess the effects of additional pharmacologic protective strategies.[125]

The bispectral index (BIS), which is derived from the analysis of phase and frequency interrelationships of EEG waves, was studied in patients undergoing cardiac surgery with CPB. BIS showed a reduced need for anesthetics after the initiation of CPB compared with before CPB.[126] This important observation was confirmed in patients by using the patient state index (PSI), another measure used to detect a patient's level of hypnosis.[127] Monitoring DHCA patients with PSI revealed that after rewarming and termination of CPB, the level of anesthetic sedation might last several hours without any additional administration of anesthetics. This might be due to the combination of deep hypothermia and pharmacologic protection with barbiturates, which is the authors' common practice. Since anesthetics may cause myocardial depression and unwanted hypotension as a result of vasodilatation, monitors such as BIS and PSI have the capacity to improve outcomes by preventing unnecessary anesthetic intervention in the early post-CPB period.

A second monitoring method to assess cerebral cooling and lowering of $CMRO_2$ that has been studied intensively is jugular venous bulb oxygen saturation ($SjVO_2$). $SjVO_2$ is measured by inserting a catheter percutaneously in the internal jugular vein and advancing it in a retrograde fashion into the jugular bulb. The actual measurements of $SjVO_2$ are performed intermittently by sampling from the catheter or continuously by using a fiber-optic catheter.[128] During cerebral cooling, the cerebral metabolic rate and cerebral oxygen extraction both decrease, resulting in an increase in $SjVO_2$. Some authors suggest that cooling during DHCA should continue until $SjVO_2$ has increased to at least 95 percent, indicating sufficient global cerebral hypothermia, although regional differences still will go undetected.[129]

The cerebral protective effect of hypothermia is undisputed,[130] but the specific temperature to guarantee maximal protection during DHCA is unknown. Hypothermia not only lowers the brain energy demands by lowering $CMRO_2$ but also provides protection by reducing excitatory neurotransmitter release, decreasing free radical production, and maintaining cellular integrity.[131] Most authors indicate that DHCA is started at a temperature of 15°C to 20°C measured at core, tympanic, or both sites.[121,132,133] The disadvantages of lower temperatures include fewer autoregulatory mechanisms and longer CPB times with resultant coagulopathies and cellular edema. Studies of neurologic deficit after DHCA conclude that an arrest time of 25 to 30 min is probably the maximally tolerated ischemic period, particularly for the brain. The duration of DHCA time and the age of the patients are reported to be the most important risk factors for mortality and postoperative neurologic deficit.[120,121,132]

To diminish cerebral ischemic time, perfusion of the brain during deep hypothermia has been implemented, including retrograde cerebral perfusion (RCP) and ASCP. Recent reports indicate the superiority of ASCP,[134–136] with neurologic deficit rates of 5 to 8 percent[132] and transient brain dysfunction rates of 10 to 30 percent.[120,135] Cerebral autoregulation is significantly better preserved with ASCP than with RCP or with no selective cerebral perfusion.[133] An alternative approach using the axillary artery for antegrade perfusion during DHCA has shown promising results[137] even in emergency conditions.[138] In addition, this technique of ASCP has allowed the recent trend away from very low temperatures toward higher systemic temperatures, up to 25°C with selective cold (15°C)[139,140] or even moderate hypothermic (25°C)[141] perfusion of the brain, to prevent temperature-induced coagulopathy and loss of cerebral autoregulation.

In spite of these improvements, the substantial residual neurologic problems after surgery with deep hypothermia have inspired researchers to focus on the rewarming phase after circulatory arrest. Several studies using $SjVO_2$ monitoring have reported significant venous desaturation during rewarming.[142,143] Apparently, there is a discrepancy between oxygen demand and oxygen supply in this crucial phase that was reported to be prevented by mild hypercapnia,[144] with a critical limit of desaturation defined as 50 percent.[142] Changing the rate of rewarming had no effect on the reduction of jugular venous saturation, indicating that a relative impairment of cerebral blood flow in the presence of marked hemodilution may be responsible for this phenomenon. Although there are no convincing data showing that jugular venous desaturation is related to postoperative neurologic deficit, a study using preoperative MRI suggested that patients with greater preoperative abnormalities had higher degrees of desaturation during rewarming.[145] Since patients undergoing surgery on the aortic arch may show preoperative impairment of cerebral perfusion, they represent a vulnerable group for venous jugular desaturation during rewarming after DHCA. Large, prospective multicenter studies may show a relationship between these two variables.

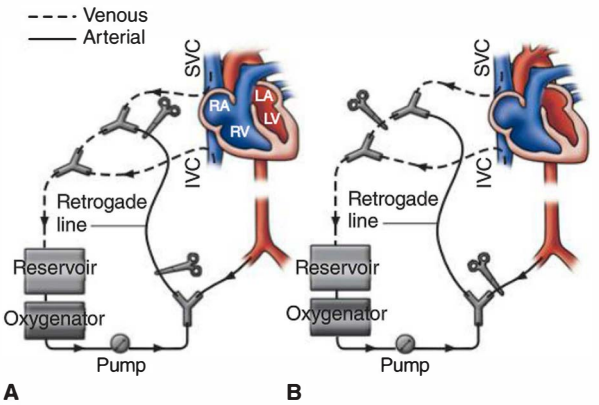

**FIGURE 39-13** Retrograde cerebral perfusion. Schematic for retrograde cerebral perfusion via the superior vena cava (SVC). **A.** Cannulation configuration for cardiopulmonary bypass and retrograde cerebral perfusion (RCP). The retrograde line is primed and clamped. **B.** RCP through the SVC after arterial return is directed through the retrograde line into the SVC. LA, left atrium; LV, left ventricle; RV, right ventricle; RA, right atrium; IVC, inferior vena cava.

***Retrograde Cerebral Perfusion.*** RCP was described by Mills and Ochsner in 1980 as a treatment for massive air embolism during CPB.[146] Intermittent and later continuous RCP was adopted by Ueda and associates[117] as a method for cerebral protection during procedures involving the aortic arch. Before the emergence of ASCP, RCP was used commonly as an adjunct to DHCA during surgery on the thoracic aorta as a way to improve neurologic outcomes. In RCP, oxygenated blood is delivered to the brain in a retrograde manner via a cannula placed in the SVC (Fig. 39-13). The hypothetical neuroprotective mechanisms of RCP include maintenance of cerebral hypothermia, washout of embolic air or debris, cerebral perfusion, and metabolic support. However, on the basis of human and laboratory investigations, the neuroprotective mechanisms of RCP remain controversial. Compared with ASCP, RCP seems to be less effective but still provides somewhat more brain preservation than does DHCA, probably as a result of the continued cerebral cooling via the venoarterial and venovenous collateral circulations.[147]

***Antegrade Selective Cerebral Perfusion.*** The earliest attempts to repair the aortic arch relied on complex methods of extracorporeal cerebral perfusion. In 1957, DeBakey and associates[15] reported a successful resection of an aortic arch aneurysm using normothermic CPB achieved by means of several pumps and bilateral cannulation of both the subclavian and carotid arteries. Eventually, the CPB perfusion technique was simplified by Dubost and associates[148] and Pearce and associates[149] by using a single pump with a Y-connection of the arterial line; however, over the next two decades, extracorporeal cerebral perfusion during aortic arch replacement was overshadowed by the growing interest in and utilization of circulatory arrest and deep hypothermia.[147]

In 1986, Frist and associates[150] from Stanford initiated the new ASCP "era" by incorporating a CPB technique with partial brachiocephalic perfusion, with low CPB flow (30 to 50 mL/kg/min) and moderate systemic cooling (26°C–28°C).[147] The arterial line from a single pump head had a Y-shape to perfuse both the femoral artery and either the innominate or the left carotid artery. In 1991, Bachet and associates[151] introduced a procedure that employed cold blood "cerebroplegia," which was perfused via the innominate and left common carotid arteries through separate pumps and heat exchangers. Kazui and colleagues[118] are credited with advancing the current use of ASCP by introducing the employment of separate arterial pump heads for the cerebral and systemic circulations to provide individual hypothermic perfusion to each system at 25°C (Fig. 39-14). Cerebral perfusion was achieved by means of endoluminal cannulation of the brachiocephalic and left common carotid arteries while the left subclavian artery was clamped or occluded with a Fogarty catheter to avoid the steal phenomenon. In an elegant experimental study, Tanaka and associates[152] provided laboratory evidence supporting the use of ASCP and outlined important perfusion details such as the optimum perfusion flow rate, pressure, and temperature.

***Pharmacologic Protection.*** Because deep hypothermia, including ASCP, often leads to an unwanted neurologic outcome in patients with circulatory arrest, additional strategies of neuroprotection are applied, including pharmacologic interventions. The cerebral protective effects of barbiturates in global ischemia have been studied in various models, including in humans after cardiac arrest.[153] All the trials failed to demonstrate an improvement in outcome. There are no randomized clinical studies showing advantageous effects

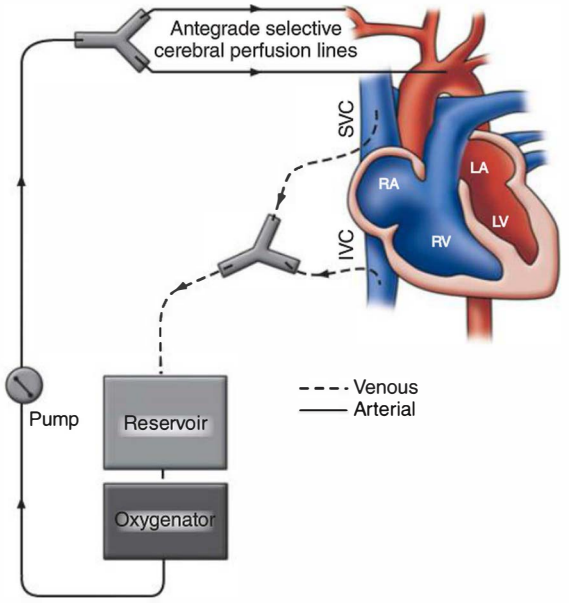

**FIGURE 39-14** Antegrade cerebral perfusion. Schematic for antegrade selective cerebral perfusion via the right axillary artery and the left common carotid artery. LA, left atrium; LV, left ventricle; RV, right ventricle; RA, right atrium; IVC, inferior vena cava.

of barbiturates in DHCA patients, and it has been suggested that barbiturates may jeopardize the energy state of the brain in patients with these conditions.[154] Still, in a survey on current practice, 35 percent of the respondents believed there was sufficient evidence to support the use of barbiturates in aortic surgery with DHCA.[155] As potential support for the use of barbiturates, it could be stated that barbiturates have been shown to be protective in patients with incomplete, focal ischemia in specific settings such as those which are present during CPB because of multiple emboli. In addition, they may be helpful in protecting the brain during rewarming after DHCA, particularly in the early phase, when the observed jugular venous oxygen desaturation mentioned above indicates a lack of oxygen delivery.

Steroids, in particular dexamethasone and methylprednisolone, are used routinely during DHCA surgery,[155] mainly because they counteract the systemic inflammatory response (SIRS) during and after CPB. Brain ischemia is considered to be a combination of embolization and SIRS, and steroids have been shown to improve the neurologic outcome in DHCA patients.[156]

## SPECIFIC OPERATIVE CONSIDERATIONS

***Replacement of the Ascending Aorta.*** Once stable CPB has been established, left heart venting is accomplished through either a pulmonary artery vent or a right superior pulmonary venous vent (Fig. 39-15). A balloon-tipped catheter is inserted into the right atrium and positioned in the coronary sinus for the delivery of retrograde cardioplegia. Adjunctive $CO_2$ perfusion of the operative field may be used. After myocardial protection is assured by instituting intermittent cold coronary sinus perfusion plus topical hypothermia, the ascending aorta is cross-clamped proximal to the origin of the innominate artery. The aorta then is transected proximal to the aortic clamp (leaving a cuff of circumferential aortic tissue to suture) and at the STJ. A Dacron tube graft that is selected to match the diameter of the aorta is anastomosed end to end to the distal aortic cuff with running 4-0 polypropylene sutures, commencing on the left side, passing along the posterior wall to the right, and being completed along the anterior wall. If the aortic wall integrity is suspect, a 4- to 5-mm strip of polytetrafluoroethylene (PTFE) felt may be incorporated in the distal suture line to minimize blood loss from suture pull-through. If aortic valve replacement or repair is necessary, it is performed. The proximal anastomosis then is performed by trimming the tube graft at the appropriate length, followed by suturing to the proximal aorta with a 4-0 polypropylene suture. Once again, if aortic wall integrity is suspect, incorporation of PTFE felt for reinforcement is recommended. Just before completion of the proximal anastomosis, the pulmonary artery vent is

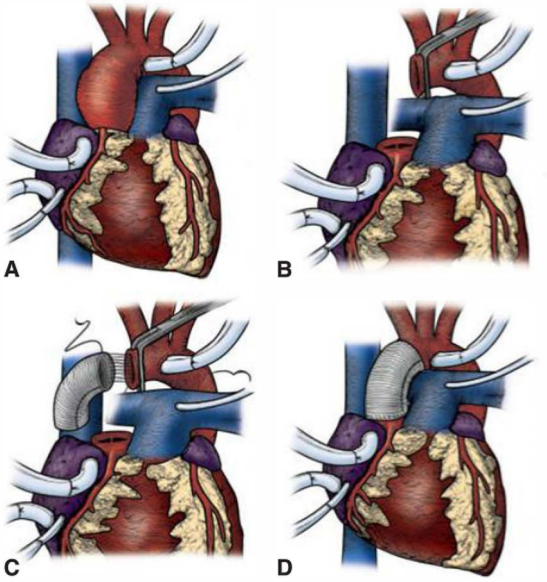

**FIGURE 39-15** Ascending aortic replacement. **A.** Routine cannulation with arterial cannulation in the underside of the midarch. Bicaval cannulation and retrograde cardioplegia are used, as well as a pulmonary artery vent. **B.** After cross-clamping the aorta and instilling cardioplegia, the aortic valve, sinuses of Valsalva, coronary ostia, and sinotubular junction are all ascertained to be normal. **C.** Full-thickness cuffs of proximal and distal aorta are fashioned, and then an end-to-end anastomosis with an appropriately sized woven Dacron graft is constructed, utilizing running 4-0 monofilament sutures. **D.** An aspirating needle in the highest point of the graft allows evacuation of air before discontinuation of the bypass. (Illustration by Simon Kimm, MD.)

discontinued, the heart is filled with blood, and standard de-airing procedures are carried out. The proximal suture line then is tied; a needle vent is placed in the graft and connected to cardiotomy suction to expel any residual air with the patient in the Trendelenburg position. Finally, the aortic crossclamp is removed from the graft, allowing reperfusion of the coronary circulation. Strict attention is paid to avoiding left ventricular dilation until cardiac ejection commences. Once rewarming has been completed, CPB is terminated, followed by removal of cannulas and the achievement of hemostasis. Hemorrhage can be a serious problem after repair despite meticulous surgical technique. Consequently, the application of local hemostatic factors (e.g., thrombin-impregnated Gelfoam, Avitene, or Surgicel) in addition to the appropriate administration of procoagulant factors is often necessary.

***Replacement of the Ascending Aorta and Aortic Root.*** Once stable CPB has been established, a left heart vent is placed and a balloon-tipped catheter is inserted into the right atrium and positioned in the coronary sinus for the delivery of retrograde cardioplegia (Fig. 39-16). After the aorta is cross-clamped proximal to the origin of the innominate artery, the myocardial preservation techniques that were described previously are instituted. The aorta is completely transected proximal to the aortic clamp (leaving a cuff of circumferential aortic tissue to suture) and just above the level of the main coronary artery ostia. The aortic valve then is excised, and a CVG repair commences. For a mechanical valve, a Dacron valved conduit is sutured into the annulus with 2-0 pledgeted horizontal mattress sutures. For a biological valve, a porcine root replacement is instituted with interrupted 3-0 horizontal mattress sutures. The left and right coronary artery orifices are excised from the aorta, leaving a 4- to 5-mm rim of aortic wall. Approximately 1 to 2 cm of the coronary arteries are mobilized carefully to avoid tension; the left coronary button is anastomosed to the valved conduit, using a running 5-0 polypropylene suture. To avoid traction and subsequent distortion of the right coronary artery, the distal graft anastomosis is completed before the right coronary button anastomosis is performed. Therefore, the valve conduit is measured, transected, and sutured end to end to the distal aorta with a running 4-0 polypropylene suture and allowed to fill retrograde, followed by the right coronary button anastomosis. Just before the completion of this suture line, the heart is filled with blood and standard de-airing maneuvers are performed. A needle vent connected to cardiotomy suction is placed in the graft, and any residual air is expelled with the patient in the Trendelenburg position. Finally, the aortic crossclamp is removed from the graft, allowing reperfusion of the coronary circulation. Once rewarming has been completed, CPB is terminated, followed by removal of the cannulas and achievement of hemostasis.

***Replacement of the Ascending Aorta and Aortic Root with a Homograft or Xenograft.*** In patients with infective endocarditis and aortic root dilation, homograft aortic root replacement is a good option after radical debridement of all infected or devitalized tissue. The proximal end of the graft is sutured to the native aortic annulus with interrupted or continuous 4-0 polypropylene sutures. Occasionally, the suture line is reinforced with a strip of pericardium to ensure hemostasis and the aortic homograft is placed in the natural position without rotation. The homograft anterior mitral valve leaflet can be utilized to patch erosions into the septum after meticulous debridement. Anastomoses are then created between the native left and right coronary artery ostia and the corresponding coronary ostia of the aortic homograft. Extension with a Dacron tube graft sometimes is used to replace the entire diseased aorta. For implantation of a xenograft, refer to Chapter 32.

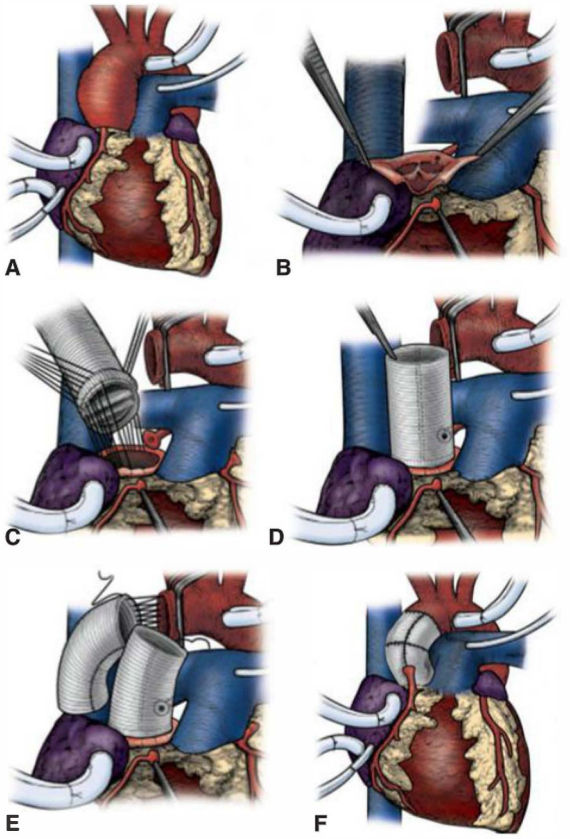

**FIGURE 39-16** Replacement of ascending aorta and aortic root. **A.** An ascending aortic aneurysm that involves the sinuses of Valsalva. Cannulation is as in Figure 35-13, but because of aortic regurgitation, antegrade cardioplegia is delivered via a hand-held cannula. **B.** The dilated coronary sinuses along with the diseased aortic valve are excised. **C.** A composite valve graft is then sewn with interrupted, everting pledgeted 2-0 mattress sutures to the aortic annulus. **D.** Full-thickness coronary buttons are fashioned, with the left button reimplanted first. **E.** The distal anastomosis with a running 4-0 polypropylene suture, utilizing a separate graft, which allows an end-to-end Dacron anastomosis using different size grafting materials for the proximal and distal anastomosis. **F.** The repair is complete after the graft-to-graft anastomosis, and a tension-free reimplantation of the right coronary button is performed. (Illustration by Simon Kimm, MD.)

**TABLE 39-3: Techniques for Reestablishing Coronary Flow in Ascending Aortic Aneurysms**

| Technique | Description |
|---|---|
| Classic Cabrol | Two coronary ostia connected in an end-to-end fashion with Dacron interposition graft, which is then anastomosed side to side with the aortic conduit |
| Modified Cabrol | Coronary ostial buttons are mobilized, sutured end to end with a smaller Dacron tube graft, and then anastomosed side to side with the aortic conduit |
| Kay–Zubiate | Individual coronary button anastomosed end to end with an interposition graft of autologous vein, then an end-to-side anastomosis with the aortic conduit |
| Dacron interposition | Individual coronary button anastomosed end to end with an interposition graft of Dacron, then end-to-side anastomosis with the aortic conduit |

***Reestablishing Coronary Flow.*** Frequently, with large aneurysms or false aneurysms, the coronary ostia are laterally displaced from the new aortic lumen. This distance can make primary attachment of the coronary ostia to ascending graft difficult even after adequate mobilization with full-thickness aortic buttons, especially in reoperative patients. Therefore, coronary flow can be established with various techniques (Table 39-3 and Fig. 39-17). Cabrol and coworkers[157] originally described connecting the two coronary ostia end-to-end with a separate Dacron interposition graft that then was anastomosed side-to-side to the aortic conduit; the entire repair was wrapped in the aneurysm wall to control bleeding. The modified Cabrol technique involves resecting the entire aortic wall and forming coronary ostial buttons, which are mobilized, sutured end-to-end with a smaller Dacron tube graft, and anastomosed side-to-side with the aortic conduit.[158] Alternatively, the Kay–Zubiate technique[159] relies solely on autologous tissue; saphenous vein is employed as an interposition graft for the displaced coronary ostia. In the absence of infection and particularly in reoperative aortic root operations in which adequate mobilization of the coronary buttons is impossible, a short interposed segment of a 6- or 8-mm Dacron™ graft works nicely.

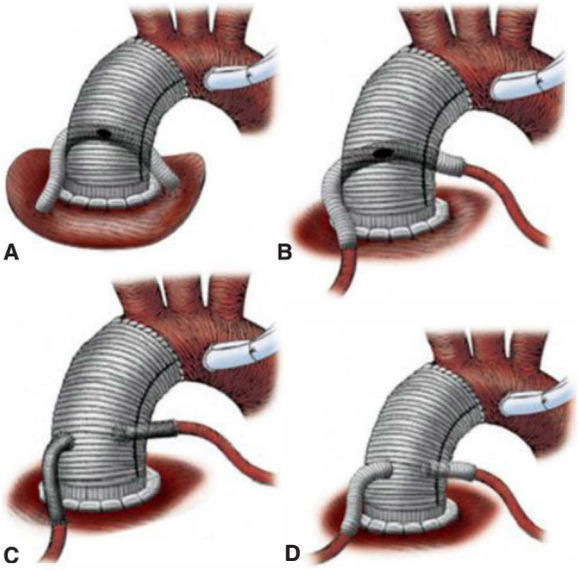

**FIGURE 39-17** Alternative methods for coronary reimplantation. **A.** The classic Cabrol method, with a 6- or 8-mm graft sewn end-to-end to the coronary ostia and side-to-side to the aortic graft. **B.** Cabrol modification that utilizes the same graft sewn end to end to full-thickness coronary buttons, again with a side-to-side central anastomosis. **C.** Using short segments of saphenous vein graft to sew end-to-end to full-thickness coronary buttons to allow revascularizing coronaries that are laterally displaced that cannot be mobilized back toward the aortic graft. **D.** An alternative utilizing 6-mm Dacron conduit as an interposition graft. (Illustration by Simon Kimm, MD.)

***Axillary Artery Cannulation.*** The axillary and innominate arteries are our preferred site of arterial cannulation for CPB when either the ascending aorta or the arch is unsuitable for cannulation and/or to facilitate selective antegrade cerebral perfusion when hypothermic circulatory arrest will be utilized in the performance of an open distal anastomosis (Fig. 39-18). The technique begins with a 6- to 8-cm transverse incision approximately two fingerbreadths below the distal clavicle in the deltopectoral groove. The pectoralis major muscle is divided in the direction of its fibers. The pectoralis minor muscle is retracted laterally or divided. Using sharp dissection, the artery is dissected from the surrounding tissue. Because the axillary artery lies deep to the axillary vein, it is usually necessary to mobilize and retract the vein. Care is taken to preserve elements of the brachial plexus or to avoid disrupting lymphatics, especially in females. Proximal and distal control of the axillary artery is obtained, and 5000 units of heparin is administered intravenously. A longitudinal arteriotomy is performed, and a 6- or 8-mm Dacron side graft is anastomosed end-to-side to the axillary artery with 5-0 polypropylene suture. The vascular clamps are removed from the artery, restoring flow to the right arm, and the Dacron graft is filled with heparinized saline solution. A 3/8″-1/4″ connector is inserted into the graft, secured with heavy ligatures, and connected to the CPB circuit. At the termination of CPB, the graft is amputated just proximal to the anastomosis, leaving a 2- to 3-mm cuff that is oversewn with

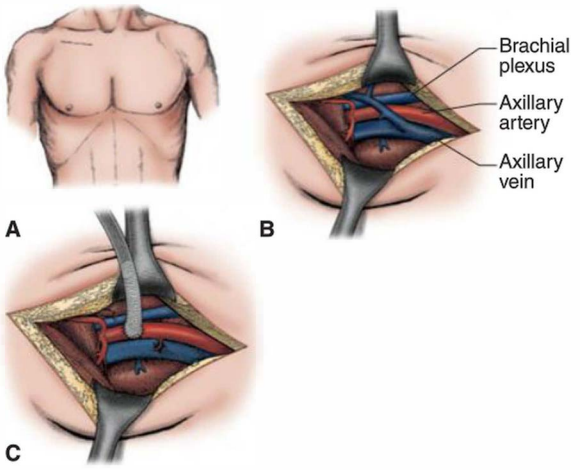

**FIGURE 39-18** Axillary artery cannulation. **A.** Infraclavicular incision on the right in the deltopectoral groove. **B.** Axillary artery is dissected from behind the overlying axillary vein, which then is clamped with a partially occluding side-biting clamp, allowing an end-to-side anastomosis with a 6- or 8-mm Dacron graft (**C**). This graft then can be cannulated for an arterial cannulation site. (Illustration by Simon Kimm, MD.)

a double layer of 5-0 polypropylene suture. The clavipectoral fascia, subcutaneous tissue, and skin are closed in three separate layers with a running absorbable suture.

***Open Distal Anastomosis and Replacement of the Aortic Arch.*** The open technique to create the distal anastomosis is required when aortic arch or hemiarch reconstruction is indicated. Upon completion of axillary artery cannulation, midline sternotomy, mediastinal dissection (including exposure of the proximal innominate artery and left carotid artery), and venous cannulation (bicaval, two stage, or femoral) are performed. The patient is cooled systemically to a target temperature of approximately 22°C. In the interim, the ascending aorta is fully mobilized and cross-clamped distally. An aortotomy is performed to decompress the aneurysm proximally and a diastolic arrest of the heart is induced by using cold blood cardioplegia via antegrade, retrograde, and/or handheld ostial delivery in concert with topical hypothermia. The aortic root is dissected further with excision/debridement of aortic valvular elements and dissection/mobilization of the coronary buttons. Replacement of the aortic root and reimplantation of the coronary buttons may proceed at this point or be deferred, based on when systemic cooling is complete. When the target temperature is achieved, the patient is placed in the Trendelenburg position and the innominate artery is clamped proximally, arresting flow to the body and permitting selective antegrade cerebral perfusion via the right common carotid artery and the right vertebral artery to proceed at a flow rate of 5 mL/kg/min. The aortic crossclamp is removed, and diseased distal ascending and aortic arch tissue is excised. Back bleeding through the left common carotid may be absent, suggesting an incomplete circle of Willis, or may be present but falsely reassuring if it is derived from collateral flow via the external carotid system. Therefore, to enhance antegrade cerebral perfusion, an appropriately sized pediatric coronary sinus catheter is placed into the left carotid artery via its takeoff from the aortic arch, secured in place by insufflation of the balloon cuff, and further bolstered by an extrinsic Silastic vessel loop. The loop is connected to the arterial inflow, providing an additional source of antegrade cerebral perfusion at 5 mL/kg/min. Higher cerebral temperatures may require selective antegrade cerebral blood flows of up to 20 mL/kg/min.

Depending on the integrity and caliber of the ostia of the great vessels, they may be reimplanted together as an "island" (Fig. 39-19A) or a "peninsula" (transverse arch or hemiarch replacement; Fig. 39-19B) as well as individually (in the setting of total aortic arch replacement). If chronic dissection is present, the septum between the true and false channels of the descending thoracic aorta is excised, providing a common channel. For total aortic arch replacement, it is often convenient to utilize a prefabricated branch graft, which may provide enhanced flexibility and efficiency in configuring the arch reconstruction (Fig. 39-19C). In any event, the distal

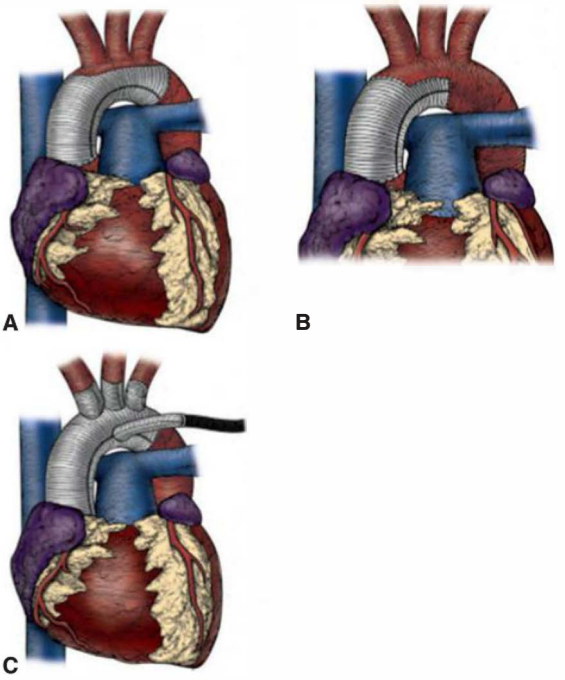

**FIGURE 39-19** Multiple methods for aortic arch reconstructions. **A.** A complete arch replacement with distal end-to-end anastomosis and reimplantation of left subclavian, left common carotid, and innominate arteries as an "island" patch. **B.** The hemiarch or "peninsula" technique. **C.** An alternative method utilizing a multibranch graft with individual anastomoses to the left subclavian, left carotid, and innominate arteries, utilizing the fourth branch as a perfusion port. (Illustration by Simon Kimm, MD.)

aortic anastomosis is constructed by using a felt reinforced 4-0 polypropylene suture technique. Great vessel reimplantation is performed with a 6-0 polypropylene running suture. After completion of the arch anastomoses, antegrade flow into the graft is commenced and gradual rewarming is initiated while the proximal aortic reconstruction is completed.

In the setting of known descending thoracic aortic disease that is likely to require future operative repair, an "elephant trunk" distal aortic repair should be utilized (Fig. 39-20). In this technique, a 5- to 10-cm cuff of Dacron graft is left in the native descending thoracic aorta to provide a proximal anastomotic site for future intervention (open repair via left thoracotomy or stent graft via an endoluminal approach). An appropriately sized Dacron tube graft is chosen. Stay sutures are placed on the proximal extent, which is intussuscepted into the distal portion of the graft destined to serve as the elephant trunk. The graft in this intussuscepted configuration is inserted into the distal aorta, and a running 4-0 polypropylene anastomosis is fashioned between the native aorta and the indwelling double-layer tube graft. The intussuscepted proximal portion of the tube graft is retrieved from the descending thoracic aorta by placing traction on the previously placed stay sutures. The remainder of the aortic arch reconstruction proceeds as described previously.

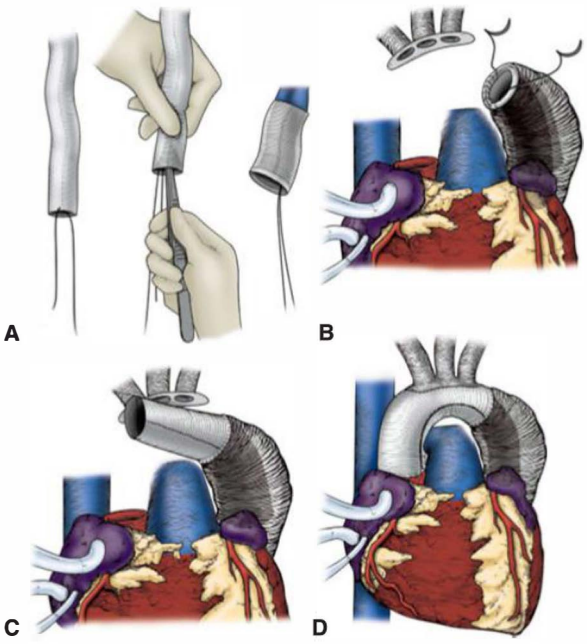

**FIGURE 39-20** Complete arch replacement utilizing the elephant trunk technique. Initially, an appropriate-length graft is intussuscepted into itself (**A**) and then placed into the proximal descending thoracic aortic aneurysm, and the distal anastomosis is constructed to full-thickness aorta (**B**). The arch part of the graft then is withdrawn from the elephant trunk, and the arch vessels are reanastomosed in the preferred manner (**C** and **D**). This method facilitates subsequent operations, as necessary, on the descending thoracic aorta. (Illustration by Simon Kimm, MD.)

Upon completion of the distal aortic reconstruction, the pediatric coronary sinus catheter is removed, a crossclamp is applied across the graft, and the innominate artery is reopened with full flow to the body restored. The distal graft then may be cannulated (with a right-angle SoftFlow cannula, a curved metal-tip aortic cannula placed via stab incision, or the accessory limb of a prefabricated branch graft) to assist in CPB and rewarming for the remainder of the procedure. At this point, attention is redirected to completion of the aortic root replacement, performance of a graft-to-graft anastomosis (running 4-0 polypropylene suture), and completion of coronary reimplantation.

## OUTCOMES/PROGNOSIS

### Results of Operation

#### ASCENDING AORTIC ANEURYSMS

Replacement of the ascending aorta has been demonstrated to be a safe and effective procedure for the treatment of chronic aneurysmal disease of the ascending aorta, with operative mortality rates of 2 to 5 percent in the most successful series.[160–162] The operative mortality varies with the acuity of the operation, patient age, left ventricular function, and the extent of operation.[23] The late survival rate after operation is approximately 65 percent at 5 years and 55 percent at 7 years.[160,163–165]

***Marfan Syndrome.*** Before 1968, the outlook for patients with MFS who required surgical repair of aneurysms or dissections involving the aortic root was bleak because of the high operative risk, the nearly prohibitive bleeding rates, and the frequent occurrence of serious postoperative complications.[2] With the advent of CVG repair, valve-sparing aortic root replacement, and modern CPB and myocardial protection, survival is excellent when the operations are performed in an experienced thoracic aortic surgical center.

***Composite Valve Graft Repair.*** In a landmark paper by Gott and associates,[166] the safety and efficacy of aortic root replacement surgery with a CVG technique in MFS patients were outlined. The mortality rate for elective root replacement in 455 patients was a remarkably low 1.5 percent, but the rate was much higher (11.7 percent) in those requiring emergency surgery for acute or chronic type A dissections, emphasizing the importance of early, elective root replacement before ascending dissection. Long-term survival after prophylactic aortic root replacement is also quite favorable, probably because the CVG configuration provides no nidus for clot formation, minimizing the risk of late cerebrovascular accidents. In contrast, MFS patients who have had aortic dissection have a significantly reduced long-term survival, which has been reported at 50 to 70 percent at 10 years.[167,168]

***Valve-Sparing Aortic Surgical Repair.*** Yacoub and subsequently David pioneered what is termed generically as

valve-sparing aortic root replacement. The two surgical approaches are distinct: The Yacoub procedure is referred to as the remodeling technique, and the David procedure is called the reimplantation technique. Both procedures are options for almost all patients with aortic root aneurysms if the aortic valve is structurally normal, but the David procedure protects against further annular dilation. If AR is present because of STJ dilation or cusp prolapse, the AR can be corrected by restoring the normal STJ geometry, shortening the cusp free margin, or both. Structurally abnormal cusps are a contraindication for the procedure, as is an aortic annulus greater than 27 to 29 mm, and CVG with a mechanical valve remains the operation of choice for patients who require anticoagulation for other conditions.[2]

Recent outcome reports from both Yacoub's and David's institutions indicate that the operative mortality rate for either procedure is low, but the need to return to the operating room for bleeding was sixfold higher after a Yacoub remodeling than after a David reimplantation (18 vs 3 percent).[169,170] Probably this is secondary to the long-exposed suture lines running up the aortic pillars and down into the individual sinuses. For prophylactic aortic repairs, long-term survival is excellent with either technique.

The main issue facing patients and clinicians who are deciding between a mechanical CVG and a valve-sparing technique is the durability of the preserved aortic valve. Data from the Yacoub group indicated that 22 percent of patients had moderate AR at follow-up (median follow-up of 3 years).[170] The presence of mild AR early after surgery portended a progression to more severe AR over time. The prevalence of late AR was lower in David's series, but 25 percent of patients at 10 years had 3+ to 4+ AR.[170] A trend toward less AR favored the David reimplantation technique over the Yacoub technique. Another clinical endpoint reflecting valve durability is reoperation. In David's series, it is remarkable that no valve-sparing patient required reoperation, but only nine patients remained at risk at 8 years. This result was superior to Yacoub's experience, in which 17 percent of patients required reoperation by 10 years (17 patients at risk at 10 years). The low numbers of patients who could be evaluated at the late term make these figures suspect secondary to large standard errors. Larger studies with longer term follow-up will be necessary to see if it is possible to assess fully the durability of these two procedures. In summary, the valve-sparing aortic root replacement may present patients with MFS with a reasonable alternative to CVG. Survival is excellent with either technique and complications are rare, but the long-term durability of this repair has not been established. Therefore, patients who select a valve-sparing procedure must accept the risk of reoperation in the future.[2]

## AORTIC ARCH OPERATIONS

As various modifications of surgical technique have been introduced, the morbidity and mortality associated with transverse aortic arch replacement have decreased over the past several decades.[17,18,171,172] Despite these recent advances, providing adequate cerebral protection and preventing cerebral embolization during reconstruction of a calcified and atherosclerotic aorta remain a formidable challenge.[173] In 10 major series, the average operative mortality rate for aortic arch replacement was 13 percent (6–23 percent).[163,174–181] For chronic aneurysms, the operative mortality rate was 11 percent (6–22 percent) and was similar for patients with degenerative aneurysms (6–22 percent) and those with chronic dissections (6–19 percent).[24] Long-term survival has been reported to range from 61 to 82 percent at 5 years and from 31 to 69 percent at 10 years.[164,182,183] Factors independently associated with a worse long-term outcome included symptomatic presentation, angina, the extent of proximal replacement, a concurrent unoperated aneurysm, cardiac dysfunction, stroke, and renal dysfunction.[164]

Contemporary series of total aortic arch replacements show increasingly impressive results, with low perioperative mortality rates and a low incidence of permanent neurologic injury (Table 39-4). These improvements are a direct result

Asc, ascending; Desc, descending; HCA, hypothermic circulatory arrest; ASCP, antegrade selective cerebral perfusion; TND, transient neurologic dysfunction.

[a]Indicates that the series contains nonemergent cases only.

[b]Indicates that the series contains elective, urgent, and emergent cases.

Modified from Spielvogel D, Halstead JC, Meier M, et al. Aortic arch replacement using a trifurcated graft: Simple, versatile, and safe. *Ann Thorac Surg* 2005;80(1):90–95.

of increasing experience, improved perioperative care, and superior myocardial and cerebral protection strategies; however, there is no consensus about the best line of attack for these complex operations, especially with regard to cerebral protection.

## SUMMARY

Ascending aorta and aortic arch pathology represents a continuing challenge for cardiovascular surgeons. Progress over the past three decades, including improved surgical instrumentation and advances in perfusion strategies with resultant improvements in myocardial and cerebral protection have augmented the surgical armamentarium significantly, facilitating the management of complex aortic problems. Increasingly, it is possible to relieve symptoms and prevent catastrophic dissection and rupture with appropriately timed prophylactic repairs even as surgeons strive to maintain more physiologic conditions with valve preservation techniques and in-line reconstructions. Significant challenges remain as surgeons attempt to increase their understanding of these degenerative processes and refine surgical procedures to allow more complex repairs while minimizing surgical morbidity.

## ASCENDING AND ARCH ANEURYSMS OF THE AORTA BOARD REVIEW QUESTIONS (CHAPTER 39)

1. Which of the following is true regarding heritable disorders of the aorta?
   A. MFS is caused by a single mutation on chromosome 15.
   B. There is enhanced expression of metalloproteinases in MS.
   C. Type II EDS is associated with vascular complications.
   D. Mutations in COLA31 cause LDS.
   E. Turner and Noonan syndromes are both autosomal recessive disorders.

2. Which is true regarding histopathology of the aorta in association with bicuspid aortic valve?
   A. Twenty percent of patients with bicuspid valve have a first-degree relative with bicuspid valve.
   B. There is a five-fold incidence of ascending aortic dilation.
   C. The valve cusps and ascending arterial media arise from the same medial crest cells.
   D. Apoptosis occurs in the valve leaflets.
   E. Fibrillin-1 deficiency is not associated with bicuspid valve.

3. Which is true for other forms of aneurysmal disease?
   A. Syphilitic aortitis is due to chronic inflammation of the adventitia.
   B. Takayasu arteritis primarily results in subclavian aneurysms.
   C. Mycotic aneurysms are typically diffuse and fusiform.
   D. The leading cause of death in Behçet disease is aneurysm rupture.
   E. Giant cell arteritis is not associated with thoracic aneurysms.

4. Which is not an indication for surgery?
   A. Symptomatic aneurysm
   B. Ten percent increase in size over 1 year
   C. Ascending aorta diameter of 4 cm in LDS
   D. Progressive aortic insufficiency
   E. Ascending aorta diameter of 4.5 cm and nonheritable connective tissue disorder

5. Which is true for outcomes after surgery for aortic aneurysm?
   A. Operative mortality for ascending aortic replacement is less than 5 percent.
   B. Long-term survival is not affected by dissection in Marfan patients.
   C. The ideal patient for a valve-sparing operation has an aortic annulus exceeding 29 mm.
   D. There is less aortic insufficiency after the Yacoub operation compared to the David operation.
   E. Chronic dissection is associated with higher mortality after arch replacement.

## ANSWERS

1. **Answer: B.** There is enhanced expression of metalloproteinases in Marfan syndrome. There are multiple mutations in chromosome 15 that can cause MFS. Type IV EDS is associated with vascular complications. Mutations in TGFBR1 and TGFBR2 are associated with LDS. Turner syndrome is a sex aneuploidy syndrome, and Noonan syndrome is an autosomal dominant condition.
2. **Answer: C.** The valve cusps and ascending arterial media arise from the same medial crest cells. Nine percent of patients will have a first-degree relative with bicuspid valve. There is a 9- to 18-fold incidence of ascending aortic dilation. Apoptosis occurs in the aortic wall. Fibrillin-1 deficiency has been implicated in matrix disruption and aortic dilation.
3. **Answer: D.** The leading cause of death in Behçet disease is aneurysm rupture. Syphilitic aortitis is due to chronic mesarteritis and periarteritis. Takayasu arteritis primarily causes occlusive disease of the arch vessels. Mycotic aneurysms are usually saccular and focal. Patients with giant cell arteritis are 17 times more likely to develop a thoracic aneurysm.
4. **Answer: E.** An isolated ascending aorta of 4.5 cm in the setting of a nonheritable tissue disorder is not an indication for surgery. All of the remaining choices are indications for surgical intervention.
5. **Answer: A.** Operative mortality for ascending aortic replacement is less than 5 percent. Dissection adversely affects survival in Marfan patients. An enlarged aortic annulus is less suitable for a valve-sparing operation. The Yacoub operation has a higher incidence of late aortic insufficiency. Chronic dissection has lower mortality compared to acute dissection after arch replacement.

# Thoracoabdominal Aneurysms

*Ying Wei Lum*
*Glenn S. Roseborough*

**KEY CONCEPTS**

- Epidemiology
  - Thoracoabdominal aneurysms (TAAs) develop in patients with atherosclerotic disease, chronic aortic dissection, and connective tissue disorders (e.g., Marfan syndrome, Ehler–Danlos syndrome).
- Pathophysiology
  - Pathologic processes include chronic inflammation, remodeling of extracellular matrix, and depletion of vascular smooth muscle cells. Elastin depletion in the media layer of the aortic wall is a common finding.
- Clinical features
  - Approximately 80 percent of TAAs are atherosclerotic in nature, associated with smoking, hypertension, hypercholesterolemia, and advanced age. Approximately 20 percent of TAAs develop from chronic aortic dissections and occur in patients with connective tissue disorders. The risk of rupture increases rapidly when aneurysmal diameter reaches or exceeds 6 cm. The most common presentation includes abdominal or back pain, although many TAAs are also discovered incidentally.
- Diagnostics
  - TAAs are classified commonly according to the anatomic scheme developed by Crawford (types I through V). Helical computed tomography and magnetic resonance angiography are the diagnostic modalities of choice, largely having supplanted angiography.
- Treatment
  - Medical therapy includes the reduction of risk factors for aneurysmal expansion (e.g., smoking, hypercholesterolemia) and tight blood pressure control predicated on the use of β-blockers.
  - Interventional therapy includes open surgical, hybrid and totally endovascular repair. Spinal cord protection is of particular concern in all methods of repair.
- Outcomes
  - In-hospital mortality rates after surgery range between 8 and 15 percent in most series. Common postoperative complications include bleeding, respiratory failure, myocardial infarction or cardiac failure, renal failure, and paraplegia. Operative risk increases with advanced age, aneurysm complexity, emergency operation, coronary and cerebrovascular disease, pulmonary disease, and renal failure. Outcomes may be improved with the distal perfusion approach to repair. Five-year survival rates range between 53 and 73 percent.

## INTRODUCTION

Since its introduction by Michael DeBakey in 1956,[1] thoracoabdominal aneurysm (TAA) repair generally presents the most technically challenging and controversial issues in vascular surgery. The surgical repair of TAAs is an undertaking that requires substantial preoperative planning and consideration of a wide array of techniques. Each of these techniques has its champions, and several authors have published comparably good results using widely different methods. In this chapter, the common principles that are applicable to all TAA surgery are described. In addition, most of the surgical techniques currently in use to repair these aneurysms are discussed, with emphasis on those that are preferred at the Johns Hopkins Hospital.

## PATHOPHYSIOLOGY

Insight into the pathophysiology of aortic aneurysm formation at the cellular level has come into focus only recently. The pathologic processes observed in aneurysm development include chronic inflammation, remodeling of the extracellular matrix, and depletion of vascular smooth muscle cells. A basic feature common to all aneurysms is the depletion of elastin, a key structural protein in the media layer of the aortic wall. Normal turnover of matrix proteins is mediated by a family of enzymes called matrix metalloproteinases (MMPs); their activity is regulated by proteins called tissue inhibitors of metalloproteinases (TIMPs). Several MMPs have elastase activity. In separate studies, MMP-2, MMP-3 (stromelysin-1), MMP-9, and MMP-12 [human macrophage elastase (HME)] have been found to have increased activity in aneurysmal tissue.[2,3]

Other components of the inflammatory response appear to play a role in aneurysm formation. The complement fixation pathway seems to be involved in matrix proteolysis, as large amounts of complement-fixing immunoglobulin G (IgG) and complement C3 have been detected in aortic aneurysms.[4] Increased amounts of the inflammatory cytokines tumor necrosis factor-α (TNF-α), TNF-β, prostaglandin $E_2$, and interleukin 6 also have been documented in aneurysm tissue.[5,6] Finally, smooth muscle cells are eliminated at least in part by apoptosis, an active process of cell death associated with increased protein synthesis. This depletes a population of cells that are capable of directing connective tissue repair.[7] All these findings suggest that aortic aneurysm formation is the result of a complex interaction of inflammatory mediators and structural components involved in maintaining the extracellular matrix.

## CLINICAL FEATURES

### Natural History

A majority of TAAs are atherosclerotic in nature and, as with abdominal aortic aneurysms (AAAs), are related to smoking, hypertension, high cholesterol, and advanced age. TAAs are the most common type of aneurysm to develop in patients previously diagnosed with AAAs, occurring in 6 percent of those patients. Approximately 20 percent of TAAs occur in patients who develop chronic aneurysmal dilatation after an aortic dissection and in patients with connective tissue disorders, most notably Marfan syndrome and Ehlers–Danlos syndrome. Compared with AAAs, the natural histories of TAAs have not been well documented owing to the lower incidence of TAAs and the fact that the advanced imaging techniques required to diagnose TAAs have been in general use only for the past two decades. In most patients, slow progressive dilatation ultimately leads to death from rupture if it is not treated (Fig. 40-1).[8–12] The other major cause of death in this population of patients is cardiac disease. The rate of aneurysmal dilatation is approximately a 10-percent increase

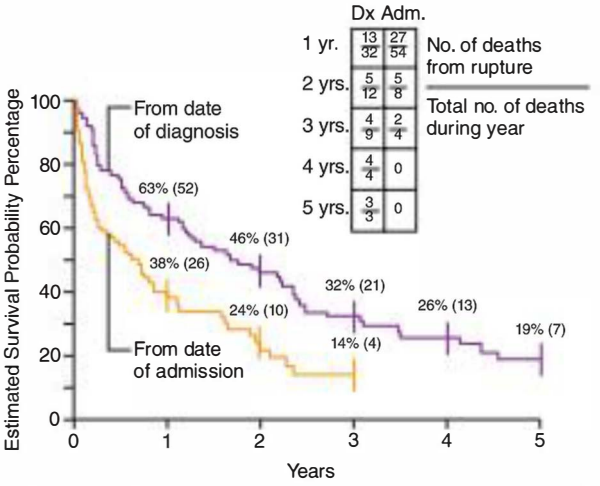

**FIGURE 40-1** Kaplan–Meier probability survival curves from date of diagnosis and date of admission in 94 patients. Numbers of patients at risk at 12, 24, 36, and 48 months are in parentheses. (Reproduced with permission from Crawford ES, DeNatale RW. Thoracoabdominal aortic aneurysm: Observations regarding the natural course of the disease. *J Vasc Surg* 1986;3:578–582. Copyright Elsevier.)

in diameter per year, with higher average rates of growth in patients with TAAs resulting from aortic dissection. The risk of rupture is related to aneurysm size. It is low below 6 cm but increases dramatically with growth in maximum diameter beyond 6 cm; most vascular surgeons recommend conservative therapy for patients with TAAs that are less than 6 cm in diameter and repair if they are more than 6 cm in patients who are acceptable surgical candidates. However, Cambria and coworkers found a higher rate of rupture in patients with TAAs larger than 5 cm.[13] TAAs that result from aortic dissection have been found to be at higher risk for rupture than are atherosclerotic TAAs in separate studies done by Crawford and Denatale and by Pressler and colleagues.[8,14] In addition, Juvonen and colleagues found that patients with TAAs resulting from chronic dissections tended to experience rupture earlier.[15] In that study, the median last known diameter of the aorta in patients who had a rupture was 5.4 cm. Additional risk factors for rupture in that study were chronic obstructive pulmonary disease (COPD) and poorly controlled hypertension. One therefore may consider repair of a TAA that is less than 6 cm in the setting of chronic dissection, particularly in a patient with poorly controlled hypertension and lung disease.

### Classification

TAAs usually are classified according to the anatomic scheme developed by Crawford and coworkers.[16] They are classified as types I through IV. A type I TAA begins in the proximal thoracic aorta and extends to the level of the celiac artery. A type II TAA is the most extensive variety, generally involves the entire thoracic and abdominal aorta, and accounts for a

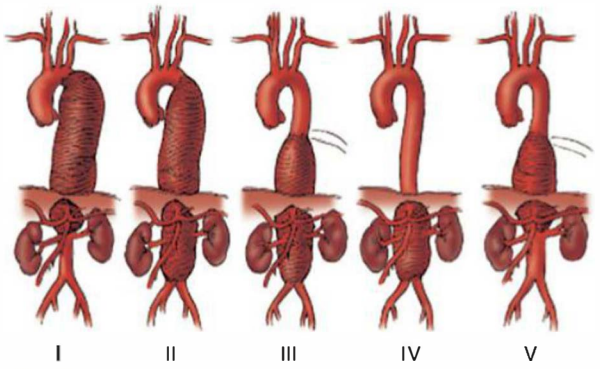

**FIGURE 40-2** Modified Crawford classification of thoracoabdominal aortic aneurysms. *Extent I:* from distal to left subclavian artery to above renal arteries. *Extent II:* from distal to left subclavian artery to aortic bifurcation. *Extent III:* from sixth intercostal space to aortic bifurcation. *Extent IV:* from diaphragm to aortic bifurcation (total abdominal aorta). *Extent V:* from sixth intercostal space to above renal arteries. (Reproduced with permission from Huynh TTT, Miller CC, Estrera AL, et al. Determinants of hospital length of stay a fter thoracoabdominal aortic aneurysm repair. *J Vasc Surg* 2002;35:648–653. Copyright Elsevier.)

large proportion of TAAs that develop years after an extensive aortic dissection. A type III TAA is defined by its proximal extent in the midthoracic aorta, generally is described in the region of the T6 vertebra or the inferior pulmonary vein, and may involve varying amounts of the abdominal aorta. A type IV TAA begins above the celiac axis and extends into the infrarenal aorta. Huynh and colleagues modified the original Crawford classification to include a type V TAA, which begins in the middescending thoracic aorta and terminates at the level of the renal arteries (Fig. 40-2).[17] This classification not only reflects what is encountered at surgery but is important for reporting results, since more extensive aneurysms generally are associated with more complications. Aneurysms that involve only the descending thoracic aorta are not included in this classification and are considered separately, although many of the same principles of TAA repair are used to repair thoracic aneurysms.

## Presentation

Most TAAs are discovered as incidental findings on plain x-ray, computed tomography (CT), or magnetic resonance imaging (MRI) studies obtained for other reasons. Up to 40 percent of patients with TAAs become symptomatic.[18] The symptoms commonly include acute abdominal or back pain. The development of severe acute pain is considered indicative of an impending rupture, and urgent repair generally is recommended within 24 h of presentation. However, the author has observed patients with histories of moderate subacute pain that had been present for weeks to months and resolved with surgical repair; it appears that not all patients with pain are at risk for imminent rupture. Less commonly, TAAs also present with gastric outlet obstruction, renal failure, aortic thrombosis, or failure to thrive. Rupture presents as acute pain with manifestations of shock or sudden death.

## DIAGNOSTIC MODALITIES

Currently, there are no recommended screening tests for TAAs because of their low incidence (1 per 100,000 population[19]) and substantial diagnostic imaging costs. Aortic aneurysms are found on plain x-ray studies about 25 percent of the time. Ultrasound is not useful since the suprarenal aorta is often difficult to image and the thoracic aorta cannot be imaged with this modality. The main diagnostic modalities used for TAAs are CT scanning, MRI, and angiography. A CT or MRI is mandatory for obtaining reliable data on the outer diameter of the aneurysm. A high-quality axial study may provide adequate information for operative planning in straightforward cases; however, helical CT or MRI angiography (MRA) with three-dimensional (3-D) reconstruction is important in defining arch involvement or pathology, especially in visceral branch vessels. Because of the high resolution of these studies, formal angiography rarely is required for preoperative planning (Fig. 40-3).

**FIGURE 40-3** Three-dimensional reconstruction of computed tomography angiogram demonstrating the anatomy of the aortic arch and visceral branches in a patient with a Crawford II t horacoabdominal aneurysm.

In the author's institution, a helical CT scan with 3-D reconstructions is the imaging method of choice. It provides virtually all the information required to plan surgical repair with data that are immediately accessible to the surgeon on a digital workstation. The software for 3-D reconstructions is very user friendly and permits retrieval and manipulation of images with minimal assistance from technicians. In contrast, MRA is slow and expensive and requires extensive postprocessing. It is more prone to false positives for occlusive disease of branch vessels, and reviewing the digital images requires extensive technical assistance. In the author's practice, MRA is reserved for patients with contraindications to CT angiography, such as contrast allergy and renal insufficiency. Aortography played an important role in preoperative planning for TAA repairs in the past, but this modality has been replaced to a large extent by the high-quality imaging of CT and MRA. Nevertheless, the author does use aortography to identify and locate the spinal artery of Adamkiewicz (see below). Recently, however, Japanese investigators have been able to identify this elusive but important structure with CT and MRA.[20,21] The author's institution has not been able to reproduce the Japanese experience reliably thus far.

## MEDICAL THERAPY

Medical therapy consists of controlling risk factors for continued aneurysmal expansion. These patients should be advised to quit smoking, and blood pressure and cholesterol should be controlled strictly. β-Blockers have been advocated to decrease the expansion rate of aortic aneurysms, but a randomized controlled trial conducted in Canada did not confirm their effectiveness.[22] Doxycycline, a known metalloproteinase inhibitor, protects against aneurysm expansion in animal models, and one randomized trial demonstrated decreased expansion rates with daily administration of this drug in a phase 2 trial.[23] However, it is premature to recommend chronic doxycycline therapy to all patients with aortic aneurysms.

## SURGICAL THERAPY

### Preoperative Evaluation and Planning

Because of the high-risk nature of TAA repair, appropriate decision making is imperative in the selection of patients for surgery and in the performance of the surgical procedure to obtain good results (see Fig. 40-4). There are three important components to preoperative evaluation and planning in TAA surgery: determining operative risk, planning the extent and technical sequence of the repair, and selecting surgical adjuncts to minimize morbidity.

The determination that TAA repair is indicated for a patient assumes that the risk of observation is greater than the risk of repair. It is therefore necessary to have a reasonable understanding of a patient's perioperative risk. Postoperative morbidity and mortality is related largely to the cardiac, pulmonary, and renal systems; hence, a thorough evaluation of those systems is imperative. At a minimum, cardiac function should be evaluated with an echocardiogram. An abnormal electrocardiogram (ECG), a history of coronary artery disease or symptoms of chest pain, congestive heart failure, or poor exercise tolerance should prompt evaluation by a cardiologist and some form of stress testing. Dobutamine echocardiography is considered to be contraindicated in patients with aneurysms because of the possibility of precipitating rupture, and so stress thallium scanning and formal exercise testing are the screening diagnostics of choice. Cardiac catheterization should be performed if reconstruction of the ascending aorta or aortic arch is anticipated. Pulmonary function tests, including spirometry and a room air blood gas, should be obtained, since single-lung ventilation usually is required intraoperatively. Renal function and hepatic function are evaluated with blood chemistries. An individualized decision to operate is based on an integration of the estimated risks of rupture and repair for a specific patient after this information has been acquired.

With TAA repair, it is imperative that the surgeon plan the entire operation in advance and anticipate the extent of and steps in the planned repair. This includes the location of the proximal and distal extent of the repair, the location and sequence of aortic clamping, and plans for reimplanting, bypassing, or reconstructing aortic branch vessels. This is important for several reasons. First, the extent of the repair will determine the level of the thoracotomy and the extent of the incision. It also will determine which adjuncts are required intraoperatively, such as cardiopulmonary bypass equipment and neurophysiologic monitoring. The most important consideration in preoperative planning relates to the pathology of the aortic arch. For TAAs involving the proximal descending thoracic aorta, it is crucial that one appreciate the patient's arch anatomy, since arch involvement may warrant the participation of a cardiac surgeon to conduct the cardiopulmonary bypass and hypothermic circulatory arrest. With extensive arch involvement, it may be necessary to perform the repair in stages. For example, in cases in which the aortic arch and the descending thoracic aorta are diseased, the arch can be replaced first, leaving a graft extension (i.e., 'elephant trunk') in the descending thoracic aorta. The descending thoracic aorta is repaired several months later, at which time the new graft replacing the descending thoracic aorta is sewn to the elephant trunk proximally. This staged approach obviates the perilous prospect of clamping and anastomosing the graft to a diseased aortic arch.

### Spinal Cord Protection

The next important consideration in preoperative planning is the way one plans to prevent spinal cord and other end-organ

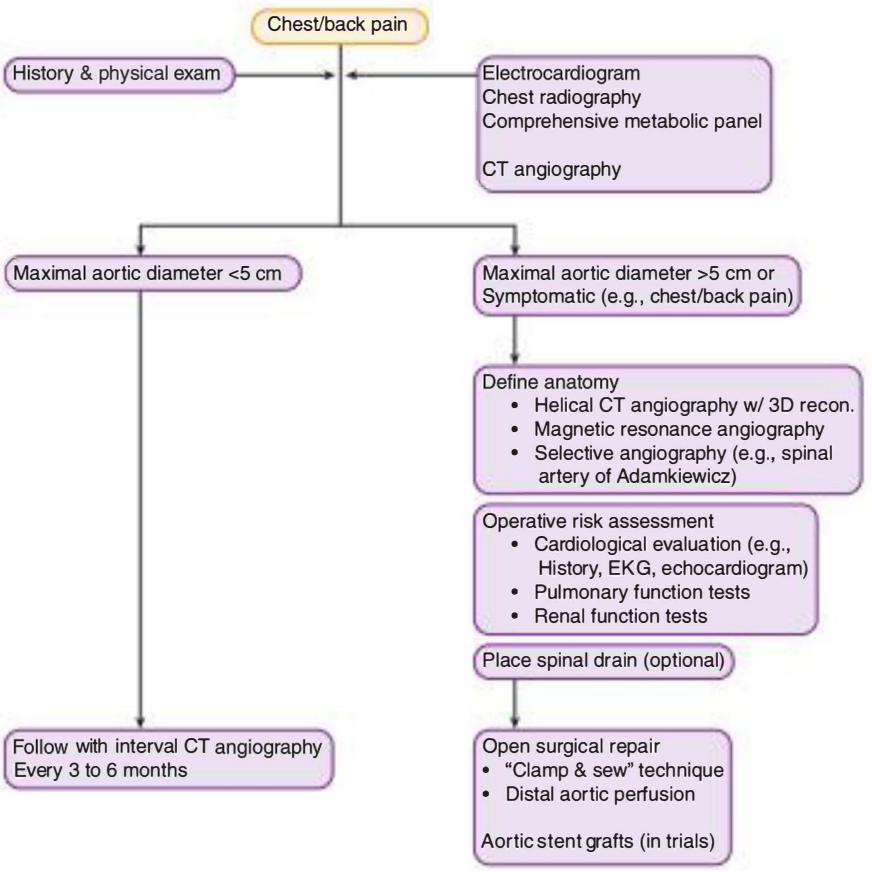

**FIGURE 40-4** Decision-making flowchart.

damage from intraoperative ischemia. Multiple strategies are available to accomplish this goal. With respect to spinal cord protection, they include (1) spinal artery conservation, (2) selective intercostal artery conservation, (3) intraoperative monitoring with somatosensory evoked potentials (SSEP) or motor evoked potentials (MEP), (4) systemic hypothermia, (5) regional hypothermia, (6) lumbar drainage of cerebrospinal fluid (CSF), (7) distal aortic perfusion, either passive or active, (8) aortic conservation with aortic 'tailoring,' and (9) pharmacologic manipulation. With respect to visceral protection, the options include regional or systemic hypothermia and distal aortic perfusion.

## SELECTIVE INTERCOSTAL ARTERY (SPINAL ARTERY) REIMPLANTATION

The most detrimental form of intraoperative ischemia that can occur during TAA repair is spinal cord ischemia, which can occur in up to 40 percent of TAA repairs. The clinical manifestations include a spectrum of spinal cord deficits that can be observed immediately after surgery or up to 3 days later. The most severe form results in complete paraplegia and usually is associated with a mortality rate over 50 percent. The spinal cord becomes ischemic as critical blood flow through intercostal arteries is interrupted when these intercostal arteries are ligated in the course of the aneurysm repair. Over 100 years ago, it was recognized that in humans, a single intercostal artery often gives rise to a branch that provides a major proportion of blood flow to the anterior spinal cord: the spinal artery or the great radicular artery of Adamkiewicz. This artery usually arises from a left-sided intercostal artery between the eighth thoracic (T8) and the first lumbar (L1) vertebrae and has a characteristic radiographic appearance. Animal studies have suggested that preserving the spinal artery can prevent paraplegia.[24] Clinical experience at the Johns Hopkins Hospital and elsewhere has confirmed that preserving the spinal artery in patients undergoing TAA repair can result in improved neurologic outcomes.[25,26] Therefore, at the author's institution, surgeons make an effort to identify the spinal artery of Adamkiewicz preoperatively by performing selective angiography of patent intercostal arteries in the lower descending thoracic aorta (Fig. 40-5). With careful technique, this blood vessel can be identified in up to 86 percent of cases.[27] All efforts are made to conserve the involved intercostal artery at the time of surgery by reimplanting or bypassing to the aortic

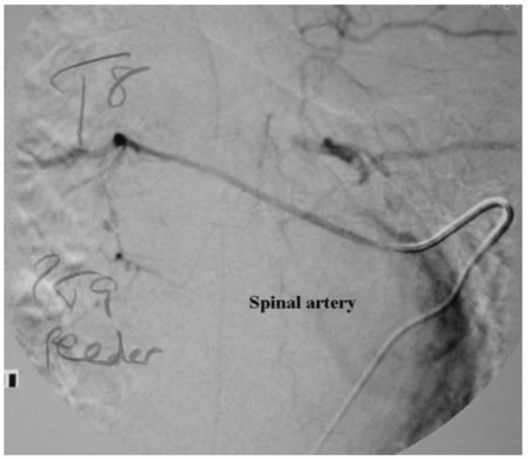

**FIGURE 40-5** Spinal artery angiogram demonstrating characteristic hairpin appearance of spinal artery of Adamkiewicz.

segment from which this intercostal arises or by including this area of aorta within the proximal or distal anastomosis. At the author's institution, it has been found that identifying and preserving the spinal artery is particularly beneficial in repairs of atherosclerotic TAAs, in which the spinal artery is more likely to be one of the few intercostals that are not chronically occluded by aortic thrombus.[28] In this subset of patients, spinal artery identification and preservation resulted in no cases of spinal cord injury in a group of 45 patients. Other authors dispute the value of identifying and preserving the spinal artery.[29,30]

## NONSELECTIVE INTERCOSTAL ARTERY REIMPLANTATION

If the spinal artery is not identified, consideration still is given to reimplantation of intercostal arteries in the lower thoracic region. Safi and colleagues and Cambria and coworkers have shown in separate studies that intercostal artery reimplantation in the T8 to L1 region improves neurologic outcomes,[31,32] and Jacobs and colleagues have reported outstanding results with intercostal artery reimplantation guided partially by MEP.[33,34] The disadvantage of nonselective intercostal artery reimplantation is that multiple intercostals generally must be reimplanted to assure that adequate spinal cord circulation has been maintained in this scenario. Reimplanting multiple intercostals requires a large intercostal patch, which can become aneurysmal in the future, or multiple small patches. The extra suture lines increase the length and complexity of the operation as well as the risk of bleeding. This approach is particularly unappealing to those who employ the clamp-and-sew method of TAA reconstruction, since without distal aortic perfusion, the time that is devoted to reimplanting intercostals adds to the visceral ischemic time because the visceral branch vessels generally are reimplanted after the intercostals.

## INTRAOPERATIVE NEUROLOGIC MONITORING

To help limit intercostal reimplantation, attempts have been made to use intraoperative neurophysiologic monitoring to identify important intercostals and guide selective reimplantation of those vessels. Initial attempts at neurophysiologic monitoring were performed by measuring SSEPs. Laschinger and associates published early work in dogs,[35] showing that SSEP was a sensitive detector of spinal cord ischemia and that distal aortic perfusion could prevent spinal cord ischemia. Subsequent clinical work by that group showed that SSEP loss for more than 30 min predicted spinal cord injury in TAA repair.[36] SSEP is limited in that it detects ischemia primarily in the dorsal spinal cord and can miss ischemic injury in the ventral horns of the spinal cord, where the motor tracts are situated.[37] As a result, intraoperative monitoring of MEPs has been proposed to overcome this limitation,[38] and clinically, MEP monitoring has been shown to be more accurate than SSEP monitoring in detecting spinal cord ischemia.[39,40] Most clinical experience with this technique comes from Holland, where separate groups have had excellent results using MEP to prevent spinal cord ischemia.[33,34,41–43] Using MEP to guide selective intercostal artery reattachment, Jacobs and colleagues achieved paraplegia rates of under 3 percent in a series of almost 200 patients.[34] The author's group has been using MEP since 2000 but has had difficulty reproducing those results. This group has noted a delayed appearance of abnormal MEP signals that can occur with isolated ischemia of the thoracic spinal cord.[44]

## SYSTEMIC HYPOTHERMIA

The development of a hypothermic environment around the spinal cord confers at least partial protection from ischemia during TAA repair. In animal experiments, Colon and coworkers demonstrated that systemic hypothermia protected the spinal cord from periods of ischemia up to 45 min.[45] The benefits of hypothermia can be realized at moderate temperatures (32°C) without incurring the risk of cardiac arrhythmias that occurs at lower temperatures, particularly below 30°C. Moderate hypothermia can be achieved passively or actively with a heat exchanger in a cardiopulmonary bypass circuit; the latter technique is preferred since it allows for active rewarming of the patient at the conclusion of the repair. The disadvantages of this approach include a higher propensity for bleeding stemming from the required anticoagulation and coagulopathies associated with cardiopulmonary bypass and variability in the availability of cardiopulmonary bypass support for some vascular surgeons. In the most extreme form of systemic hypothermia, TAA repair can be performed under profound hypothermia (18°C) and circulatory arrest, as advocated by Kouchoukos and coworkers in this country and by others elsewhere.[46–48] Kouchoukos and coworkers reported very low rates of spinal cord injury with this approach.[46] In the author's practice, this strategy is applied selectively to difficult distal aortic arch anatomy, since circulatory arrest is not without significant

morbidity, including neurocognitive dysfunction. Safi and colleagues reported that profound hypothermia and circulatory arrest did not offer significant benefit compared with moderate hypothermia and partial bypass.[49]

## REGIONAL HYPOTHERMIA

It is also possible to develop spinal cord hypothermia without systemic cooling by using a regional infusion of a cold solution via an epidural catheter. This technique has been championed by Cambria and colleagues at the Massachusetts General Hospital, who have been able to achieve excellent results with respect to spinal cord injury without systemic hypothermia or distal aortic bypass.[32,50,51] With this technique, it is necessary to protect the viscera during extensive TAA reconstructions with cold regional perfusion of those organs as well. Despite good published results, the technique has not been adapted widely at other centers.

## CEREBROSPINAL FLUID DRAINAGE

When the proximal thoracic aorta is clamped, the intracranial and CSF pressures rise. Conversely, blood pressure distal to the clamp drops dramatically. Spinal perfusion pressure, which is represented by mean arterial pressure of the spinal cord minus CSF pressure, therefore drops markedly. CSF drainage reduces CSF pressure in the spinal canal and therefore improves spinal perfusion pressure when spinal perfusion is low intraoperatively as well as in the postoperative period, when CSF pressure may rise as a result of the spinal cord edema that accompanies ischemia–reperfusion injury. Blaisdell and Cooley first demonstrated that decreasing spinal fluid pressure (pharmacologically with intravenous urea) can have a beneficial effect on paraplegia rates in dogs.[52] Subsequently, it was found anecdotally to be useful in resolving delayed-onset paraplegia in the early postoperative period.[53] However, a small prospective randomized study performed by Crawford and coworkers found that CSF drainage had no effect on paraplegia rates.[54] Eleven years later at the same institution, Coselli and colleagues found a statistically significant benefit with CSF drainage in a repeat study, lowering neurologic deficits from 13 percent in the control group to 2.6 percent in the treatment group.[55]

## DISTAL AORTIC PERFUSION

Two fundamental surgical approaches are employed in TAA repair: (1) the so-called clamp-and-sew approach and (2) distal aortic perfusion techniques. The clamp-and-sew method originally employed by DeBakey and Crawford has been employed for over 40 years and still is used by some accomplished aortic surgeons, particularly in patients with less extensive aneurysms.[56–59] In this approach, the aorta is clamped sequentially during the construction of the proximal anastomosis, the reimplantation of critical branches, and the construction of the distal anastomosis. Repair can be performed quickly by an experienced surgeon with less blood loss, since intraoperative anticoagulation is not necessary with this method. However, this technique can expose the viscera to perilously long ischemic times if technical difficulties are encountered with the proximal anastomosis or intercostal artery reimplantation, resulting in end-organ ischemia.

The distal aortic perfusion strategy maintains perfusion of the aorta and its branches distal to the area where the clamps are placed while an anastomosis is created. Distal perfusion can be passive or active. Examples of passive distal perfusion include the Gott aortic shunt,[60–62] an axillofemoral bypass that is constructed before the thoracotomy is begun,[63] and an 'octopus' of catheters whose proximal ends are placed in the Dacron tube graft after the proximal anastomosis is completed and whose distal ends are placed in and perfuse the orifices of the renal and mesenteric arteries while the distal thoracic aorta is repaired.[64] Active distal aortic perfusion involves pumping blood through a centripetal pump into the abdominal aorta while the thoracic aorta is clamped. At the Johns Hopkins Hospital, surgeons believe that this technique is the standard of care in TAA repair as it has several important advantages. A heat exchanger attached to the pump circuit permits active cooling of the patient and, more important, active rewarming at the end of the procedure, when hypothermia contributes to coagulopathy. The advantage of being able to rewarm the patient actively to physiologic temperatures cannot be overstated. The flow in the pump circuit can be adjusted to manipulate the blood pressure proximal and distal to the aortic cross-clamp; typical pump flows range between 1.0 and 2.5 L/min. Proximal hypertension and distal hypotension are corrected by increasing pump flow; proximal hypotension and distal hypertension are corrected by decreasing pump flow. An obstruction to inflow or outflow can be detected by high resistance that is noted in the circuit but would go undetected in a passive shunt. The circuit can be converted quickly to a full cardiopulmonary bypass circuit if the patient experiences cardiac arrest or it becomes apparent intraoperatively that circulatory arrest is required to complete a difficult proximal anastomosis near the aortic arch. Numerous centers have demonstrated improved results in TAA surgery with distal aortic perfusion, and it is the preferred adjunct in most centers.[65–69]

The author's group prefers the use of nonselective distal aortic perfusion, in which the abdominal aorta is perfused via the left femoral artery while the thoracic aortic reconstruction is performed. The patient is cooled to 32°C before spinal cord or visceral ischemia occurs. The mesenteric and renal arteries are clamped and not perfused while the segment of abdominal aorta containing those branches is reconstructed. The author's institution finds that mesenteric and renal revascularization can be accomplished within 30 to 60 min and that renal failure and clinically significant visceral ischemia rarely are encountered with this technique. However, other investigators have shown improved results with selective distal perfusion using direct cannulation of the renal and mesenteric arteries while the visceral abdominal aorta is clamped. Jacobs used selective perfusion (with isothermic blood) in 73 patients and had excellent results, with

permanent renal failure occurring in only 1 patient (1.4 percent) and transient dialysis required in 5 (6.8 percent). Koksoy and associates[70] and Hassoun and associates[71] independently undertook clinical trials to determine whether intraoperative cold perfusion of the viscera could minimize ischemic injury and improve postoperative outcomes, particularly with respect to renal function. Their techniques and findings differed, but both studies found some benefit to cold visceral perfusion. In the Koksoy trial, the kidneys were perfused with cold crystalloid containing steroids and mannitol, and the mesenteric vessels were perfused with warm blood from the left heart bypass circuit. In that study, renal failure was decreased in the cold perfusion group.[70] In the Hassoun trial, all the visceral vessels were perfused selectively with blood that had been cooled to 4°C by being passed through a heat exchanger. The investigators in that trial found no difference in the rate of renal failure but did find improved survival in the group that received cold perfusion.[71]

### AORTIC CONSERVATION

Occasionally, one encounters a moderately dilated distal thoracic aorta while replacing a large aneurysm of the more proximal thoracic aorta in which formal aortic replacement may not be warranted but it may be desirable to try to prevent aneurysmal degeneration of this distal segment to avoid additional surgery in the future. Similarly, it is sometimes necessary to operate on a nondilated aortic segment to correct malperfusion from an aortic dissection. In these situations, it is often preferable not to replace the involved aorta to avoid spinal cord and visceral ischemia. This can be accomplished by using an aortic 'tailoring' procedure developed by G. Melville Williams at the Johns Hopkins Hospital. With this approach, a longitudinal aortotomy is made (in the case of an aortic dissection, the intimal flap subsequently is resected), and the aorta is closed with to a diameter of approximately 2 cm to decrease wall tension and prevent further aneurysmal degeneration. This procedure eliminates the need to sacrifice or reimplant any aortic branches and can be performed with very short cross-clamp times. Williams and colleagues first reported this technique in the treatment of patients with chronic dissecting aneurysms[72] and then applied it to the management of acute aortic dissections complicated by malperfusion.[73] Surgeons at the author's institution routinely tailor a segment of aorta that is up to 4 cm in diameter and occasionally tailor even larger segments. Since Williams began performing this procedure, reoperation has not been required on any tailored segments for subsequent aneurysmal degeneration, with the exception of patients with connective tissue disorders; such disorders, including Marfan syndrome and Ehlers–Danlos syndrome, are contraindications to the aortic tailoring approach.

### PHARMACOLOGIC ADJUNCTS

Most surgeons administer intravenous mannitol before any identified periods of renal ischemia. Mannitol is an osmotic diuretic and free radical scavenger that preserves urine flow after renal ischemia. It does not necessarily prevent ischemic renal failure but promotes a nonoliguric state that is easier to manage clinically.[74–80] In addition, mannitol can ameliorate pulmonary injury associated with aortic surgery.[81]

Acher and coworkers use the partial opioid agonist naloxone for neuroprotection during TAA reconstruction, which they perform with the clamp-and-sew technique and routine ligation of all intercostal arteries. They reported excellent results, with paraplegia rates of 3 percent,[56] although their experience has not been duplicated elsewhere.

A host of pharmacologic agents that interfere with the ischemia–reperfusion injury process have been tested for their ability to prevent spinal cord injury, and they are reviewed thoroughly by de Haan.[82] There are no uniform recommendations for the use of any of these agents. At the author's institution, it has been found that diazoxide, a mitochondrial potassium–adenosine triphosphate (ATP) channel opener, protects against ischemic spinal cord injury in a rabbit model.[83] Further work has shown that this effect is achieved through decreased production of reactive oxygen species in the mitochondria (unpublished data). Current research in cardiology and neurology has focused on poly-adenosine diphosphate (ADP) ribose polymerase (PARP), an enzyme that participates in multiple cellular pathways involved in DNA repair, apoptosis, and ischemic preconditioning. This area of investigation shows promise for improvement in outcomes with respect to partial or delayed neurologic deficits that result from a modest ischemic (and subsequent reperfusion) injury to the spinal cord.

## Operative Technique

The author's protocol for surgical TAA repair begins 2 days before surgery with spinal angiography. A spinal drain is placed by the anesthesiologists the day before surgery so that if a bloody tap occurs during drain placement, there is time for the hemorrhage to resolve without postponing or canceling the operation. After anesthetic induction, the patient is intubated with a single-lumen endotracheal tube that then is exchanged for a double-lumen endotracheal tube to permit single-lung ventilation. Proper placement of the tube is confirmed bronchoscopically. A double-lumen endotracheal tube is important not only to collapse the left lung to facilitate exposure of the aorta in the left chest but also to prevent blood and secretions from depositing in the left lung. Bronchial blockers do not provide reliable isolation of the left lung throughout these long operations and are not recommended.

A Swan–Ganz pulmonary artery catheter and additional central venous lines are placed. A radial arterial catheter always should be placed in the right arm, since a catheter in the left radial artery becomes useless if is necessary to clamp the aortic arch between the left carotid artery and the left subclavian artery. A transesophageal echocardiogram probe is placed, and the patient is put in the right lateral decubitus position on a beanbag with the left arm padded on a Kraus

retractor. The spinal drain is connected to a drainage apparatus with a pop-off valve set to 5 to 10 cm $H_2O$. The hips are rotated obliquely to keep the right groin in the surgical field. The left chest is prepped to the axilla superiorly, the spine posteriorly, and the sternum anteriorly. The abdomen is prepped to the right of the midline. Both groins are prepped to provide surgical access to the femoral vessels. A cell-saver and a rapid infuser should be readily available in the operating room.

The incision is determined by the proximal extent of the aneurysm. In situations where the proximal clamp is placed on or just distal to the aortic arch, as in a type I or type II TAA or for chronic dissection arising just beyond the left subclavian artery, a standard posterolateral thoracotomy is done. The chest is entered in the fourth intercostal space to allow satisfactory exposure of the aortic arch. A type III TAA may be approached through a sixth or seventh interspace incision, whereas a type IV TAA may be approached through an eighth or ninth interspace incision. The incision is carried down onto the abdominal wall, across the oblique muscles lateral to the left rectus abdominus muscle. The retroperitoneal plane is entered deep to the transversus abdominus muscle and developed posteriorly to the psoas muscle under the diaphragm. It is easy to enter the peritoneal cavity inadvertently at this point, especially medially by the edge of the rectus abdominus muscle, where the peritoneum is thin and adherent. The costal margin is divided with heavy scissors, connecting the left chest cavity to the retroperitoneum, and the left internal mammary artery is ligated.

A single simple thoracotomy incision rarely provides enough exposure to repair an extensive TAA. The author's preference is to perform a subperiosteal resection of the rib above or below the interspace that is entered, depending on where exposure is needed most. Additional exposure is provided by 'notching' an additional rib adjacent to the excised rib; a 2-cm segment is excised subperiosteally near the costospinal junction. This approach usually provides adequate exposure to repair even the most extensive TAA. Other surgeons recommend performing a double thoracotomy through one or two skin incisions or a stepwise thoracotomy, in which two or more ribs are divided vertically to extend the thoracotomy through more than one interspace.[84] A self-retaining retractor is placed in the wound and is critical to maintaining exposure of the large field in these long cases: The Omni, Thompson, and Buchwalter retractors are examples of such retractors.

After the chest is entered, ventilation of the left lung is arrested to collapse the lung. The aneurysm, left lung, and heart are inspected. There can be extensive adhesions between the lung and the aneurysm. Filmy adhesions are taken down to mobilize the lung off the aneurysm. If the adhesions are dense, lysis of them can cause extensive intrathoracic and intrapulmonary hemorrhage, and it may be necessary to work around the lung and even open the aneurysm without mobilizing the lung off it. The diaphragm is divided to expose the entire thoracoabdominal aorta, joining the left pleural cavity and the retroperitoneum into a single operative field. This can be done in two different ways. A radial incision can be made from the anterior edge of the diaphragm where the costal margin is divided directly down to the aortic hiatus. This incision is simple to close but results in paralysis of the diaphragm lateral to the incision. Alternatively, the diaphragm can be taken down peripherally, leaving a 2-cm cuff along the chest wall all the way to the aortic hiatus. This is the preferred incision at the author's institution because it preserves the function of the diaphragm and has a minimal effect on postoperative respiratory function, facilitating repair of TAAs in patients with even marginal respiratory status.

The patient then is placed on partial (left heart) bypass with a Bio-Medicus centripetal pump circuit. The inflow site for the cardiopulmonary bypass pump circuit can be one of three sites: the proximal descending thoracic aorta, the left atrium, or the left inferior pulmonary vein. Aortic cannulation can be hazardous, especially in a diseased aorta, and can lead to extensive bleeding while the cannula is in place or after it is removed. The author never cannulates the ascending aorta or the aortic arch because of difficulty with exposure and the risk of stroke. Atrial cannulation requires a pericardiotomy and manipulation of the heart. The preferred site at the author's institution is the left inferior pulmonary vein, which can be accessed in an extrapericardial location. It is easy to locate after division of the inferior pulmonary ligament and mobilization of the lower lobe of the left lung, although occasionally it cannot be used because of adhesions in this area. The patient is anticoagulated systemically with 100 to 150 U/kg of intravenous heparin, and an activated clotting time (ACT) is checked. A pledgeted purse-string suture of 2-0 Ticron is placed in the left inferior pulmonary vein, and the vein is opened after the anesthesiologist delivers a Valsalva breath to prevent air embolism. An angled Sarns venous cannula (20F to 24F) is placed into the pulmonary vein through the purse-string suture and connected to the inflow limb of the pump circuit.

Outflow of the cardiopulmonary bypass circuit usually is delivered via the left common femoral artery. An oblique groin incision is made, and the left femoral artery is dissected out by an assistant while the thoracotomy is being performed. The artery can be cannulated directly, but the author prefers to isolate the artery and sew an 8-mm Dacron graft end to side onto it. A straight 22F or 24F aortic cannula is inserted into and secured to this graft. This technique decreases the chance of creating a dissection in the iliofemoral system and permits antegrade perfusion of the left leg as well as retrograde perfusion up the left iliac system, eliminating the ischemia of the left leg that results from direct cannulation. It also allows the perfusionist to keep the pump circuit flowing into the left leg at a rate of at least 500 $cm^3$/min if it is necessary to clamp the left iliac system during the distal aortic reconstruction.

There are four basic steps in surgical TAA repair: construction of the proximal anastomosis, ligation/reimplantation of thoracic intercostal arteries, reimplantation or bypass of the renal and mesenteric arteries, and construction of the distal anastomosis. One must determine preoperatively if the aortic arch is involved; this will necessitate the involvement of a cardiac surgeon to conduct full cardiopulmonary bypass

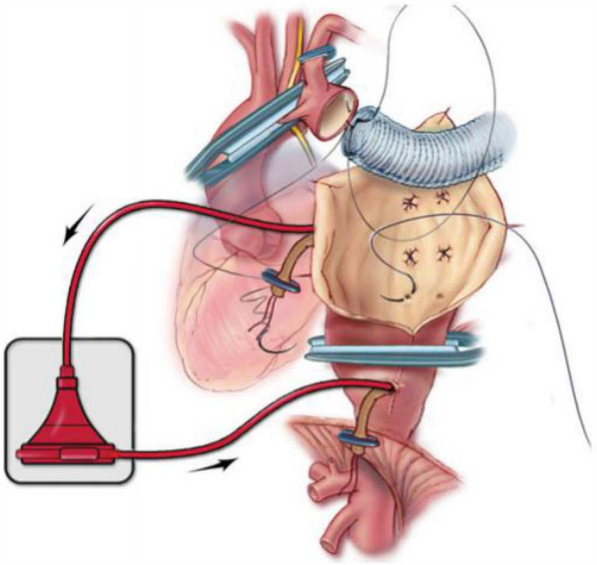

**FIGURE 40-6** Illustration of the construction of the proximal anastomosis during the repair of the descending thoracic aorta just beyond the left subclavian artery. Left heart bypass can be used to provide distal aortic perfusion during the repair. The venous cannula can be placed in the left atrial appendage or left inferior pulmonary vein, and the aortic cannula can be placed in the femoral artery or distal aorta. The upper intercostal arteries generally can be oversewn safely down to the level of T8. (Reproduced with permission from Cohn LH, ed. *Cardiac Surgery in the Adult*, 4th ed. New York: McGraw-Hill, Inc.; 2012.)

and circulatory arrest to effect repair. An aneurysm or dissection that begins just beyond the left subclavian artery may be repaired with a proximal cross-clamp on the aortic arch between the left common carotid artery and the left subclavian artery (Fig. 40-6). This is generally safe but does entail a risk of stroke and recurrent laryngeal nerve injury.

The distal cross-clamp is placed just beyond the level of anticipated aortic transection to minimize distal ischemia during the construction of the proximal anastomosis. The anastomosis between an appropriately sized Dacron tube graft and the proximal aorta is constructed in an end-to-end fashion with running 3-0 polypropylene (e.g., Prolene) sutures. The author prefers to reinforce the anastomosis with strips of Teflon felt incorporated circumferentially in the suture line.

Once the proximal anastomosis is completed and tested for hemostasis, the distal thoracic aorta is repaired. The smooth conduct of this portion of the operation is critical to minimize the risk of paraplegia. Upper left-sided intercostal arteries are ligated before the thoracic aorta is opened if they can be reached behind the aorta, but this can be difficult and can lead to bleeding. The author attempts to dissect out lower left-sided thoracic intercostal arteries and clamp them with atraumatic vascular clamps to prevent back bleeding and steal from the spinal cord circulation, but this is not always possible. The right-sided intercostal arteries are virtually never accessible external to the aorta. The distal clamp is moved to the level of the diaphragm, and the aorta is opened and inspected for patent intercostals branches. The upper intercostal arteries generally can be oversewn safely down to the level of T8 (Fig. 40-6). If the location of the spinal artery is known, the intercostal artery supplying that vessel is reimplanted into the Dacron tube graft with a side-to-side anastomosis or by means of a short interposition graft placed between the Dacron tube graft and a patch of tissue around the relevant intercostal artery; the other intercostal arteries are oversewn. If the spinal artery is not found, serious consideration is given to reimplanting any patent intercostal arteries between the T8 and L1 levels. In this situation, surgeons at the author's institution usually try to reimplant at least one or two pairs of intercostal arteries in the distal thoracic aorta, particularly large ones that back bleed poorly (Fig. 40-7). It may

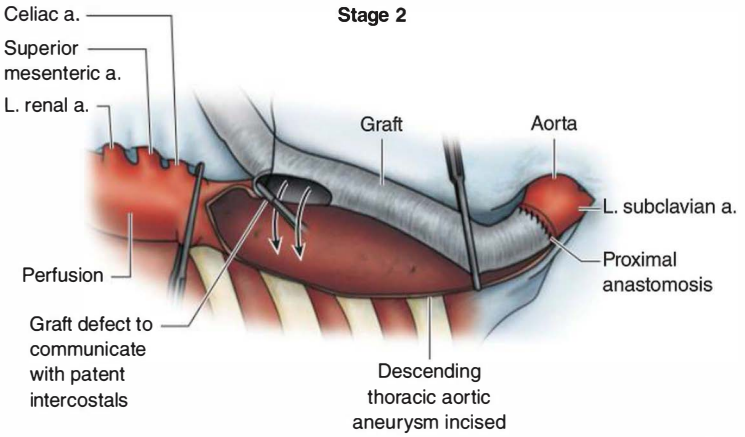

**FIGURE 40-7** Illustration depicting reimplantation of critical intercostal arteries in the side of an aortic graft as a Carrel patch. The abdominal aorta and visceral organs are being perfused during this stage of the procedure by the aortofemoral bypass circuit. (Reproduced with permission from Frank SM, et al. Moderate hypothermia, with partial bypass and segmental sequential repair for thoracoabdominal aortic aneurysm. *J Vasc Surg* 1994;19: 687–698. Copyright Elsevier.)

be necessary to thrombectomize or endarterectomize the aorta to identify patent intercostals. Jacobs employs MEP monitoring to guide selective clamping and reimplantation of intercostal arteries that may be critical to spinal cord perfusion and has reported excellent results, with paraplegia rates of 3 percent.[34] Surgeons at the author's institution have employed MEP since 2000 but have found it to be much less accurate in predicting spinal cord injury. Similar efforts using SSEP monitoring have been even less rewarding. This portion of the operation can take an hour or more, resulting in prolonged visceral ischemia if distal aortic perfusion is not employed.

The visceral abdominal aorta is repaired next. The distal clamp is moved to the most proximal location that will permit repair; if the TAA terminates at the celiac artery, the clamp is placed above the renal arteries so that the kidneys are perfused continuously by the left atrial–femoral bypass circuit. Usually, the clamp is placed below the renal arteries, resulting in visceral and renal ischemia. The celiac and superior mesenteric arteries are dissected out and clamped or controlled from within the aorta with Fogarty balloon catheters once the aorta has been opened. The renal arteries do not back bleed significantly and thus do not need to be controlled. If the TAA terminates near those branches, they can be incorporated into the distal anastomosis. If it extends into the infrarenal aorta, they are reimplanted into the side of the graft (Fig. 40-8). The configuration of the reimplantation depends on the amount of dilatation in this region. With less extensive aneurysms, the celiac, superior mesenteric, and renal arteries can be reimplanted into the side of the graft as a single patch. More often, the celiac, superior mesenteric, and right renal arteries are implanted as one patch and the left renal artery is implanted as a second patch. With extensive aneurysms in this region, the mesenteric vessels are implanted as a single patch and the two renal arteries are implanted as separate patches. The left kidney usually is implanted last and therefore is subjected to the longest ischemic times.

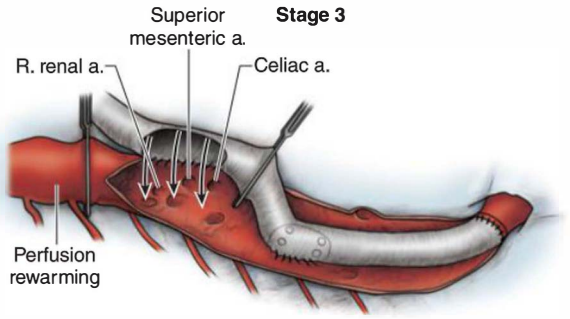

**FIGURE 40-8** Illustration depicting reimplantation of the mesenteric and renal arteries in the side of an aortic graft. Occasionally this can be accomplished as a single patch, but two, three, or even four inclusion patches may be necessary to reimplant the vessels. (Reproduced with permission from Frank SM, et al. Moderate hypothermia, with partial bypass and segmental sequential repair for thoracoabdominal aortic aneurysm. *J Vasc Surg* 1994;19:687–698. Copyright Elsevier.)

Reimplantation of the visceral vessels usually can be accomplished within 30 to 60 min. In these cases, bowel infarction and permanent renal failure are very rare, and so surgeons at the author's institution do not selectively perfuse or shunt the visceral vessels routinely during the visceral vessel reconstruction. Ischemic times increase with the number of patches and can exceed an hour with a difficult reconstruction. If prolonged visceral ischemia is anticipated, consideration should be given to perfusion of the viscera by means of selective catheterization of these vessels and perfusion with either cold blood or crystalloid when the visceral aorta first is opened, as this may reduce the incidence of postoperative renal failure and increase survival rates.[70,71,85] If there is aneurysmal involvement of the branch vessels, interposition grafting from the main Dacron tube graft to those vessels may be required. Surgeons at the author's institution have reported ruptures of aneurysms of the visceral patches, and so they now make every effort to limit patch size, especially in Marfan's disease patients.[86]

Once the visceral patch anastomoses have been completed, the graft is de-aired by back bleeding the mesenteric vessels, and the cross-clamp is placed on the graft at a point distal to the patch anastomoses to permit antegrade visceral perfusion. The distal anastomosis then is performed end to end to the infrarenal aorta if the aneurysm terminates there. If there is iliac artery involvement, a bifurcated graft is sewn to the iliacs first; the proximal end then is anastomosed end to end to the distal aspect of the more proximal Dacron graft. Exposure of the right iliac artery can be difficult from thoracoabdominal incisions and may require a retroperitoneal incision in the right lower quadrant to effect the repair. In cases of iliac artery involvement, every effort is made to revascularize the hypogastric arteries, since spinal cord perfusion may be dependent on the hypogastric circulation after intercostal arteries and lumbar arteries are divided.[34]

After the visceral arteries are reimplanted, the patient is warmed actively with the heat exchanger on the cardiopulmonary bypass circuit while the distal anastomosis is being completed. Once the patient reaches 36.5°C, the bypass circuit is clamped and heparinization is reversed with protamine. The cannula in the pulmonary vein is removed while a Valsalva maneuver is performed. The graft on the femoral artery is clamped and divided, leaving a 1-cm stump of graft on the femoral artery, which then is oversewn. The diaphragm is closed with a heavy running suture after the patient is taken out of the flexed position. The thoracoabdominal and groin incisions are closed in standard fashion. Left apical and basal chest tubes are placed in the left chest, and an Axiom sump drain is placed in the retroperitoneum. The patient's double-lumen endotracheal tube is exchanged for a single-lumen tube before the patient is transported to the intensive care unit. The apical tube is removed on postoperative day 1 if there is no pneumothorax, as is the Axiom drain. The basal chest tube is removed when chest drainage is minimal. The spinal drain is removed on postoperative day 3.

## SPECIAL CONSIDERATIONS

### Thoracoabdominal Aneurysms Related to Chronic Aortic Dissection

TAAs related to chronic aortic dissection pose a number of special technical challenges. First, the proximal anastomosis can be very difficult to perform when the dissection originates very close to the left subclavian artery takeoff. Even cross-clamping between the left carotid artery and the left subclavian artery may not permit a satisfactory repair, and circulatory arrest with deep hypothermia may be required. The false lumen must be entered, and it may be necessary to mobilize the back wall of the aorta off the chest wall to ensure that the adventitia of the back wall is included in the anastomosis. Otherwise, one inadvertently may omit the adventitia from the back wall of the anastomosis, resulting in disastrous bleeding. Once this happens, placement of repair stitches in this area is extremely difficult, and it usually becomes necessary to redo the entire anastomosis.

Second, there are more likely to be more patent intercostal arteries in the descending thoracic aorta than is the case with atherosclerotic aneurysms. Even if the false lumen is thrombosed, it rarely involves the entire posterior wall of the thoracic aorta, leaving many patent intercostal branches. Opening the descending thoracic aorta not only results in massive blood loss from intercostal back bleeding but also may create a huge steal syndrome from the spinal circulation, increasing the likelihood of paraplegia. In these cases, therefore, attempts are made to get external control of as many intercostal arteries as possible with atraumatic spring-loaded clamps before the descending thoracic aorta is opened. Once bleeding is controlled and the surgeon has decided how much of the aorta must be replaced, it can be determined whether these vessels should be reimplanted or ligated.

A third complicating factor relates to the distal intimal flap found in chronic aortic dissections. Malperfusion may result distal to the area where the intimal flap is excised unless care is taken in managing the flap at that point. If the aneurysm terminates in the infrarenal aorta or the distal thoracic aorta several centimeters above the celiac artery, the bypass is stopped temporarily, the distal clamp is removed briefly, and a V-shaped wedge is cut in the intimal flap through the open end of the aorta to stabilize the flap and turn it into a flow divider. Surgeons at the author's institution have prevented distal malperfusion with this technique.

In some cases of TAAs stemming from chronic dissection, large aneurysms of the proximal descending thoracic or the infrarenal aorta are repaired, leaving a moderately aneurysmal distal thoracic or visceral aorta. In situations where the maximum diameter of the distal aorta is dilated but less than 4 cm, surgeons at the author's institution perform a longitudinal aortotomy, resect the intimal flap, and close the aorta to a narrower diameter of 2 cm (Fig. 40-9). This 'aortic tailoring' decreases aortic wall tension, reducing the chances of further aneurysmal dilatation. Of note, in the author's experience, this strategy does not appear to be applicable in patients with connective tissue disorders. This simplified technique preserves intercostal arteries in the distal thoracic aortic segment that otherwise would have to be ligated or reimplanted, decreasing the risk of paraplegia. In the visceral segment of the aorta, the longitudinal aortotomy usually can be opened and closed in less than 20 min, a very short ischemic time that the viscera tolerates very well. This technique can be applied to other areas of the aorta but is particularly valuable in the critical areas of the lower thoracic and abdominal aorta. It also may be employed to correct acute branch malperfusion in an acute aortic dissection. In this situation, the aortic intimal flap is resected and any intimal flap that extends into the orifices of branch vessels is tacked down within the orifices.

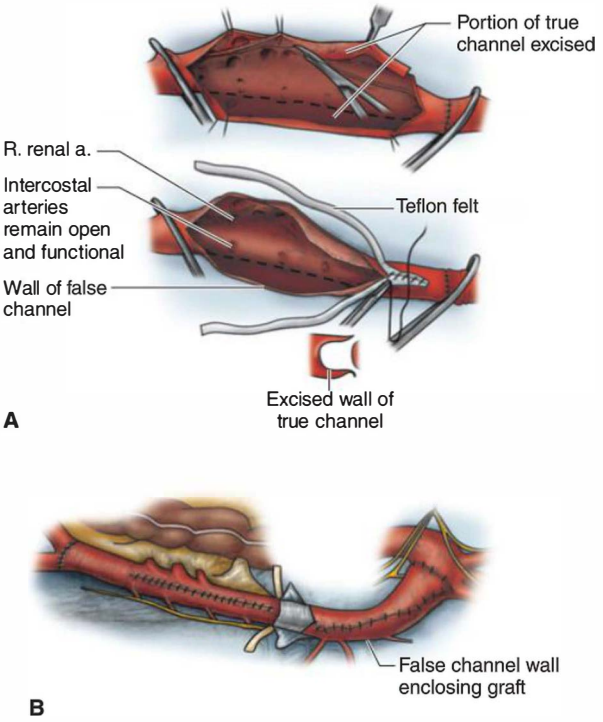

**FIGURE 40-9** Repair of an acute aortic dissection arising in an aneurysm of the descending thoracic aorta complicated by malperfusion of the mesenteric circulation. The aneurysm has been replaced proximally, and the malperfusion has been treated by means of a longitudinal aortotomy, resection of the intimal flap, and closure of the aorta to a small diameter. The suture line is buttressed by strips of Teflon felt. (Diagrams from Williams GM, Schlossberg L. *Atlas of Aortic Surgery.* Baltimore: Williams & Wilkins, 1997. With permission.)

### Ruptured Thoracoabdominal Aneurysms

Ruptured TAAs usually present formidable technical challenges. The patient's symptoms often suggest whether the rupture occurred in the thoracic or the abdominal aorta. If one discovers intraoperatively that a ruptured abdominal

aneurysm is in fact a ruptured TAA, one must first examine the supraceliac aorta at the aortic hiatus. If it is amenable to clamping and the performance of a proximal anastomosis (less than 4 cm in diameter), one should perform a medial visceral rotation to achieve exposure of the suprarenal aorta and control the mesenteric vessels. The infrarenal aorta is controlled distally, and the aorta can be replaced without circulatory bypass. If the supraceliac aorta is too diseased, the laparotomy can be converted to a thoracoabdominal incision across the left costal margin, allowing access to the fifth intercostal space if the costal margin is divided at the level of the xiphoid process. With proximal involvement of the thoracic aorta, consideration should be given to using distal bypass if it is readily available.

More often, the diagnosis of a ruptured TAA is known before exploration. In many such cases, patients have remained stable enough to undergo diagnostic imaging and transfer to a tertiary care center that has the personnel and resources to repair those aneurysms. Selective bias at least partially accounts for the fact that in many published series, the results of repairing ruptured TAAs approach those for repairing ruptured infrarenal AAAs, with survival rates in the range of 40 to 50 percent.[87–93] At the author's center, if surgeons believe the patient is stable enough, they take the additional time to place a spinal drain and neuromonitoring leads if resources are readily available. Needless to say, these judgments are made on an individual basis.

## Endovascular Thoracoabdominal Aneurysm Repair

### HYBRID PROCEDURES

Recent success with treating abdominal and thoracic aneurysms with endovascular technology, and the high complication rates of surgical repair of TAAs, has led to efforts to treat TAAs with endovascular techniques. However, the limited availability of total endovascular repairs with branched/fenestrated stent grafts has resulted in the development of hybrid operations; which combine both open and endovascular techniques (see Table 40-1). This approach consists of first 'debranching' the visceral segment of the aorta with surgical bypasses to the splanchnic and renal arteries distal to their origins. Both renal arteries, the superior mesenteric artery and the celiac are separately and sequentially revascularized with a series of bypass limbs from one or two bifurcated grafts that originate on the distal infrarenal aorta or iliac arteries. The origins of these target vessels are then ligated so that blood cannot flow back into the aorta. Then, the aneurysmal segment is excluded by deploying thoracic stent grafts from the descending thoracic aorta to the infrarenal aorta. There have now been multiple single-institution series comparing hybrid repairs to traditional open repairs for Crawford type I to IV TAAs.[94–98] The majority of these studies had enrolled patients for hybrid repairs if they were deemed unfit or high risk for traditional open surgery. Criteria used to decide if someone was unfit or high risk commonly included advanced age, poor functional status, severe chronic obstructive pulmonary disease, prior open thoracic or TAA repair, and obesity.

There have been two approaches to the timing of hybrid procedures, with some authors recommending a one-stage procedure[94,95,98] and some advocating a two-stage procedure where the visceral bypasses are performed in one operation and the aorta is excluded with stent grafts in a separate, staged procedure (interval between procedures varies from a mean of 3 days to median of 23 days).[96,97,99] Advantages of a single stage procedure include the ability to access the aorta or iliac arteries directly to deliver the thoracic stent grafts (this is an issue particularly in situations when iliac tortuosity or narrowness presents a problem for femoral access), and to ensure accurate deployment of the stent graft relative to the origin of the visceral bypass grafts. Proponents of the two-stage procedure cite several advantages to that technique, including shorter operating times,[99] as well as decreased risk of renal failure given concurrent insults from ischemic time coupled with contrast administration.[96] In addition, delaying the exclusion of the aorta may minimizes the risk of paraplegia

**TABLE 40-1: Table of Recently Published Single-Institution Series Results of Hybrid Procedures for TAAs**

known to occur with preoperative hypotension that is more likely to occur when the visceral bypasses are performed.[95]

Regardless of the timing of the approach, spinal drainage is recommended in all patients perioperatively during stent graft deployment. Other technical considerations include the choice of inflow site for retrograde visceral bypass grafting. In general, the site is determined by the distal extent of aneurysmal disease, prior abdominal aortic surgery, and the quality of native aorta and iliac arteries. If the infrarenal aorta has already been replaced, as is frequently the case, the bypass graft can be taken off the existing infrarenal graft in an end-side fashion. Otherwise the visceral grafts are taken off the most proximal normal aorta or iliac artery available, allowing several centimeters of normal aorta above this location to land the distal end of the thoracic stent graft that is used to exclude the aneurysmal aorta.

The drawbacks of hybrid procedures include the concern for endoleaks, which have been reported to be as high as 20 to 40 percent,[94,96,97,99] the unknown durability of retrograde bypass grafting, and the potential for graft enteric erosion. Furthermore, mortality and paraplegia rates for hybrid repairs remain humbling and have not consistently been shown to be better compared with traditional open repair for both high-risk and similar-risk groups.[94, 96] In addition, graft limb thrombosis of the visceral bypasses can result in renal failure or mesenteric ischemia with fatal consequences.

On the other hand, the theoretical benefits of hybrid operations compared to traditional open TAA repair include the avoidance of performing a thoracotomy and single lung ventilation in patients with borderline pulmonary function and avoidance of aortic cross-clamping. Furthermore, there is a significant benefit in terms of reduced visceral ischemic time: The ischemic time to each kidney is reduced to the time is takes to perform a single renal artery anastomosis (usually 5–10 min) and there should be no mesenteric ischemia at all since, when one mesenteric artery is being revascularized, the entire gut and visceral organs should be perfused by the other mesenteric artery via collaterals. This contrasts sharply with the visceral ischemia that occurs during visceral revascularization by the patch inclusion method during open TAA repair, which is typically on the order of 30 to 60 min. Indeed, in the largest series reported to date by Choong et al., hybrid operations have become the preferred repair for type I, II and III TAAs[98] at their institution, since this approach had significantly lower morbidity than open repair.

With a 2-year patient survival rate of less than 30 percent in untreated TAAs,[8] and until total endovascular repair options become more commonly available, such hybrid operations provide a valuable alternative for selected patients, especially some who would otherwise be deemed unfit for surgical repair of their TAAs.

## TOTAL ENDOVASCULAR REPAIR

Numerous case reports and small series have documented successful endovascular repair of aneurysms of the descending thoracic aorta,[101–106] and since obtaining FDA approval in 2005, endovascular repair of descending thoracic aneurysms has become mainstream. Endovascular repair of TAAs has been more limited because of the more complex techniques needed to achieve preservation of visceral flow. However, recent redevelopments in fenestrated and branched grafts have opened the way for a total endovascular approach to treating TAAs (see Table 40-2).

Fenestrated grafts (Fig. 40-10) are designed with nitinol-reinforced holes in the graft fabric that have to be positioned adjacent to the origin of the target visceral artery. Fenestrations, however, have no bearing on the orientation of the target artery (cranially or caudally). Branched grafts (Fig. 40-11), on the other hand, incorporate preattached limbs or cuffs that are attached to the aortic stent graft component.[111] Precise positioning of the fenestration/branch is vital to the success of this procedure and this is ensured by careful preoperative imaging and planning. Once the device is placed at the desired level/orientation of the visceral vessels under fluoroscopy, the fenestration/branch is accessed over a stiff wire into the target vessel, and through this, covered stents are placed.[108,110] This technology can also be applied to aneurysms involving the aortic arch.

Similar to reports of hybrid repairs, the experience with totally endovascular TAA repair consists of single-institution studies where the patients enrolled were deemed

unfit for open surgery. However, unlike hybrid repairs, the early mortality rates after total endovascular repair were significantly lower according to one review.[112] However, this technology is certainly not free of the complications of open repair, including paraplegia, visceral ischemia, and multiorgan dysfunction. The reported paraplegia rates are generally lower, but this may be due to the fact that most reported series contain a higher proportion of Crawford IV TAAs, which inherently are associated with lower rates of spinal cord complications. A major challenge for total endovascular repair is that complex conformational changes occur in the aneurysm after it is depressurized, which can lead to delayed endoleak from component separation, or visceral ischemia from thrombosis of the stent grafts connecting the main aortic graft to the visceral arteries. Nevertheless, the potential advantages of a totally endovascular approach over open or hybrid operations are obvious wherein no body cavities are opened along with the avoidance of aortic cross-clamping and visceral ischemia.[108] The development of this technique is certainly exciting to observe as this technique evolves from surgeon-modified devices[113] to individually custom-designed stent grafts[107–108] and to most recently, progressive reports of standardized, off-the-shelf, multibranched stent grafts.[114]

## COMPLICATIONS AND RESULTS

Despite advances in surgical technique and perioperative care, the mortality and morbidity associated with TAA repair remain high. In-hospital mortality rates vary from 8 to 15 percent in most series and may be considerably higher in subsets of patients with extensive aneurysms or comorbidities. Complications occur in up to 75 percent of these patients. Common major complications include reoperation for bleeding, respiratory failure, myocardial infarction or cardiac failure, renal failure, and paraplegia. These postoperative complications, along with preoperative complicating factors such as emergency operation, extensive aneurysms (particularly Crawford type II TAA), advanced age, renal insufficiency, coronary disease, cerebrovascular disease, and pulmonary disease, generally are associated with adverse outcomes.[16–18,32,57,59,115–118] Hospital stays in uncomplicated cases are typically 10 to 14 days and may be considerably longer when there are complications. The pioneering work of Stanley Crawford represents the gold standard for TAA repair with the clamp-and-sew technique. In 1986, Crawford published his experience with TAA repair in 605 patients using this technique.[8] Thirty-day mortality was 8.9 percent; variables predictive of early death were advanced age, prolonged clamp time, COPD, atherosclerotic heart disease, renal failure, and renal artery obstruction. Five-year survival was 60 percent, and a third of late deaths were due to cardiac disease. Renal failure requiring dialysis occurred in 5 percent of patients with normal preoperative renal function and 17 percent of patients with preoperative chronic renal insufficiency. Neurologic deficits in the lower extremities occurred in 11 percent of these patients, with complete paraplegia in 6 percent. The presence of rupture, reattachment of intercostal arteries, the presence of aortic dissection, and the extent of the aneurysm were significant variables associated with neurologic deficits. The last two variables had a particularly strong influence on neurologic outcomes with the clamp-and-sew technique. Neurologic deficits occurred in 30 percent of patients with dissections compared with 7.4 percent of patients without dissections and varied from 2 percent in patients with Crawford IV aneurysms to 28 percent in patients with Crawford II aneurysms (Table 40-3).

Adapted from Crawford ES, et al. Thoracoabdominal aortic aneurysms: Preoperative and intraoperative factors determining immediate and long-term results of operations in 605 patients. *J Vasc Surg* 1986;3(3):389–404.

Crawford's experience was updated in 1993, by which time his series included 1509 patients.[18] Once again, rupture, dissection, and the extent of aneurysmal disease were particularly predictive of perioperative death, renal failure, and paraplegia. Other groups using the clamp-and-sew approach have published similar results.[58,59] In the series of Schepen and coworkers, the hospital mortality rate was 11.4 percent, neurologic deficit occurred in 13.8 percent of patients, and renal failure occurred in 14.1 percent.[59] In the series of Mauney and colleagues,[58] hospital mortality was 13 percent, neurologic deficit was 10 percent, and renal failure requiring dialysis was 11 percent. Cambria and associates performed a thorough analysis of their series of 337 patients, in whom the clamp-and-sew technique was used in 93 percent and epidural cooling was used in 57 percent. Variables predictive of death in that series were rupture, emergent operation, intraoperative hypotension, a high transfusion requirement, spinal cord injury, major paraplegia, renal failure, and pulmonary complications.[32] Preoperative variables associated with spinal cord injury were rupture, type I and II TAA, and urgent or emergent operation; intraoperative variables included epidural cooling, sacrifice of T9–L1 intercostals, and intraoperative hypotension as well as prolonged operative time, cross-clamp time, and visceral ischemia. There is evidence that the addition of distal bypass can improve the results obtained with clamp-and-sew techniques, particularly in high-risk patients with extensive aneurysms and aortic dissections. Schepens and colleagues were able to show in their series of 258 patients that left heart bypass reduced mortality, neurologic deficits, and the need for postoperative dialysis.[68] Coselli and coworkers found that left heart bypass was particularly beneficial in patients with type II TAAs, in whom neurologic deficits were reduced from 13 to 5 percent.[69] In a separate publication, Coselli and colleagues reported that the selective use of distal bypass eliminated dissection as a risk factor for postoperative neurologic deficits.[119] Safi and coworkers also demonstrated that left heart bypass in conjunction with CSF drainage could be beneficial in preventing neurologic injury in high-risk patients.[120]

Postoperative renal failure consistently has been shown to be a strong predictor of death in all studies of TAA repair. It typically is associated with a mortality rate of approximately 50 percent. Schepens and coworkers found that age, ischemic heart disease, diabetes, and preoperative creatinine were significant predictors of postoperative renal failure by univariate analysis and were able to develop a stepwise logistic regression equation that accurately predicts the risk of postoperative renal failure by using just two variables: age and preoperative creatinine.[121] Safi and colleagues also examined this subject and found that renal failure was associated with preoperative creatinine, the clamp-and-sew technique, left renal artery reimplantation, and visceral perfusion.[122]

Long-term survival after TAA repair varies between 53 and 73 percent at 5 years. The majority of deaths are due to cardiac disease, although Svensson and associates found that aortic dissection, postoperative neurologic deficit, and renal insufficiency also adversely affected long-term survival.[18] Schepens and coworkers found that early or late reoperation for aortic-related pathology was required in 18 percent (31 of 172) of patients.[123] Cambria and associates found on long-term follow-up that 11 percent of patients (33 of 333) required reintervention after discharge for additional aortic pathology or graft-related problems.[124] Conversely, many patients develop TAAs after having an aneurysm repaired in either the distal or the proximal aorta. Coselli and colleagues examined their results in patients undergoing TAA repair as a second operation after undergoing surgery on the proximal thoracic or distal infrarenal aorta.[125] Surprisingly, they observed a trend toward better results in patients with previous thoracic aortic repair, although that group of patients was younger, had fewer comorbidities, and had fewer emergent repairs than did the group of patients who did not undergo previous thoracic repair. In the patients who underwent TAA repair after distal aortic surgery, the results were quite acceptable, with an in-hospital mortality rate of 12 percent, a paraplegia rate of 4.1 percent, and a renal failure rate of 11.4 percent. Patients also can develop aneurysms of the intercostal or visceral inclusion patches of aorta that are reimplanted onto the Dacron tube grafts. In the author's institution, it was noted that aneurysmal expansion of the inclusion patches occurred in 7.5 percent of patients on long-term follow-up, and therefore, surgeons there recommend implanting small patches of aorta onto the side of the graft, particularly in patients with connective tissue disorders.[86]

Because of the considerable intraoperative technical challenges and the complex postoperative management issues these operations present, they are best performed by experienced surgeons in centers that have extensive critical care resources. Cowan and associates studied the effect of experience (as defined by surgeon and hospital volumes) on outcomes and found that both variables had a significant effect on operative outcomes.[126] Mortality was reduced by more than half when the operations were performed by high-volume surgeons compared with low-volume surgeons; similar reductions in mortality were seen when the procedures were performed in high-volume hospitals compared with low-volume hospitals. Further demonstrating this benefit, Girardi and Coselli showed that even octogenarians can undergo TAA repair with reasonable outcomes when it is performed by an experienced surgeon in a high-volume center.[127] The importance of this volume relationship is further underscored by a recent state-wide database review by Rigberg et al.[128] Even though their report failed to show a volume relationship, they noted that the busiest institution in their database study performed only 14 cases/year and thus their data was unlikely to allow a meaningful assessment of the role of hospital volume in TAA mortality. However, they did note a statewide 30 day mortality of 19 percent, which is worse than the high-volume single-institution reviews that were previously described.

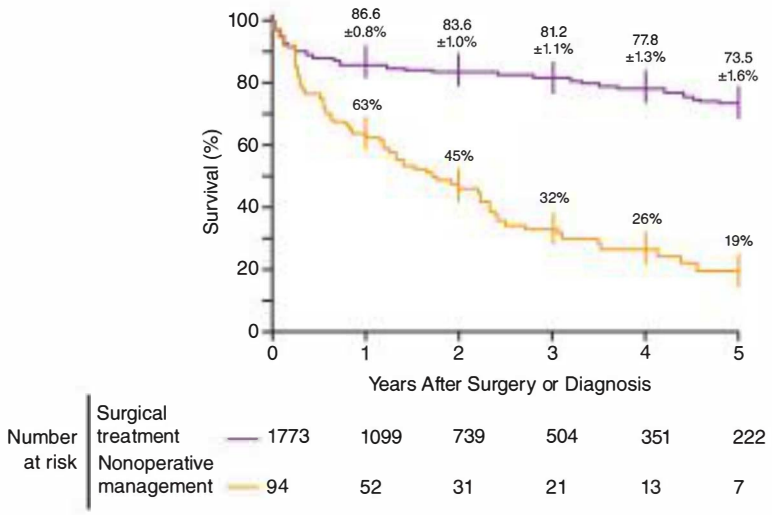

**FIGURE 40-12** Survival curves showing improved survival of a cohort of 1773 patients operated on by Coselli and colleagues compared with t he original cohort of 94 nonoperatively treated patients followed by Crawford. (Reproduced with permission from Coselli JS, Conklin LD, LeMaire SA. Thoracoabdominal aortic aneurysm repair: Review and update of current strategies. *Ann Thorac Surg* 2002;74:S1881–S1884. Copyright Elsevier.)

TAA repair does improve long-term survival, as has been demonstrated by Crawford and Denatale[8] and Coselli and coworkers,[129] but this benefit is dependent on satisfactory surgical results (Fig. 40-12). A good functional outcome is even harder to achieve. Rechtenwald and associates retrospectively studied the functional outcomes of 101 patients undergoing TAA repair over a 6-year period.[130] They found that only 63 percent of patients experienced a good functional outcome at the time of discharge, and that number dropped to 52 percent 1 year after discharge. The results were compromised by a hospital mortality rate of 18 percent and a 12-percent incidence of neurologic deficits; the poor 1-year outcomes were due largely to a 1-year mortality rate of 33 percent. Good functional outcomes correlated with good surgical outcomes; predictors of good outcome were elective operation, short visceral ischemic times, normal preoperative and postoperative renal function, use of left atrial femoral bypass, and absence of postoperative neurologic deficits and pulmonary dysfunction.

## SUMMARY

Repair of TAAs is a challenging exercise that requires considerable preoperative planning, intraoperative skill, and meticulous postoperative care. With a combination of surgical adjuncts, good immediate and long-term results can be achieved. Although there are a number of options for surgical management of these patients, the author's preferred approach includes preoperative CT angiography, selective spinal artery angiography, intraoperative neurophysiologic monitoring, selective spinal artery reimplantation when appropriate, empiric intercostal artery reimplantation when no spinal artery is found, aortic conservation with aortic tailoring in select circumstances, and intraoperative distal aortic perfusion to minimize visceral end-organ ischemia. Postoperative mortality and complications such as cardiac, renal, and respiratory failure as well as spinal cord injury continue to be significant problems. Future advances in the pharmacologic manipulation of ischemia–reperfusion injury as well as the paradigm shift in the development of new endovascular techniques will provide further improvements in the management of these challenging patients.

## THORACOABDOMINAL ANEURYSMS BOARD REVIEW QUESTIONS (CHAPTER 40)

1. Which is a correct classification of thoracoabdominal aneurysm?
   A. Type I involves the entire thoracoabdominal aorta.
   B. Type II begins at the proximal thoracic aorta and ends at the celiac artery.
   C. Type III begins above the celiac artery and extends into the infrarenal aorta.
   D. Type IV begins in the midthoracic aorta and extends into the abdomen.
   E. Type V begins in the midthoracic aorta and ends at the level of the renal arteries.

2. Which is correct for techniques for intercostal artery reimplantation?
   A. The spinal artery usually arises from a right-sided intercostal artery between T8 and L1.
   B. The spinal artery can be identified in 50 percent of patients using angiography.
   C. Preservation of the spinal artery is not particularly beneficial in repair of an atherosclerotic aneurysm.
   D. A large intercostal patch can become aneurysmal over time.
   E. Nonselective implantation of intercostal arteries between T4 and T7 has been shown to improve neurologic outcomes.

3. Which is true regarding techniques for spinal cord protection?
   A. SSEP detects ischemia in the dorsal spinal cord.
   B. MEP is less accurate than SSEP.
   C. Profound hypothermia and circulatory arrest provides significant benefit compared to moderate hypothermia and partial bypass.
   D. CSF drainage has no effect on paraplegia rates.
   E. Distal aortic perfusion provides no improvement over clamp and sew.

4. Which agent has been shown to be beneficial in multiple trials?
   A. Mannitol
   B. Naloxone
   C. Diazoxide
   D. PARP
   E. Nitroglycerin
5. Which is true regarding outcomes after surgery for thoracoabdominal aneurysm?
   A. In-hospital mortality is 5 to 10 percent.
   B. Complications occur in about 40 percent of patients.
   C. Neurologic deficits occur in about 20 percent of patients.
   D. Five-year survival averages between 50 and 70 percent.
   E. Over 80 percent of patients have a good functional outcome at discharge.

## ANSWERS

1. **Answer: E.** A type V aneurysm, as modified by Huynh and colleagues, begins in the midthoracic aorta and ends at the level of the renal arteries. A type I aneurysm begins at the proximal thoracic aorta and ends at the celiac artery. A type II aneurysm involves the entire thoracoabdominal aorta. A type III aneurysm begins in the midthoracic aorta and extends into the abdomen. A type IV aneurysm begins above the celiac artery and extends into the infrarenal aorta.
2. **Answer: D.** A large intercostal path can become aneurysmal over time. The spinal artery can be identified in over 85 percent of patients using angiography and usually arises from a left-sided intercostal artery between T8 and L1. Both preservation of the spinal artery and nonselective implantation of intercostal arteries in the T8 to L1 region have been shown to improve neurologic outcomes.
3. **Answer: A.** SSEP detects ischemia only in the dorsal spinal cord and is therefore less accurate than MEP. Profound hypothermia and circulatory arrest was not shown to have significant benefit by Safi and colleagues when compared to moderate hypothermia and partial bypass. CSF drainage was shown by Coselli and colleagues to have a significant benefit on paraplegia. Numerous centers have shown improved results with distal aortic perfusion.
4. **Answer: A.** Mannitol is the only agent that has been shown in multiple trials to be effective for both renal and pulmonary protection.
5. **Answer: D.** Five-year survival is about 50 to 70 percent. In-hospital mortality is 8 to 15 percent. Complications occur in up to 75 percent of patients, with only about 10 percent of patients suffering a neurologic deficit. Good functional outcome at discharge is present in approximately 60 percent of patients.

# 41 Aortic Dissection

*Thoralf M. Sundt III*

## KEY CONCEPTS

- Epidemiology
  - Aortic dissection is the most common fatal disease process of the aorta. Increasing awareness of the clinical impact of the condition is reflected by the coining of the term "acute aortic syndrome" (AAS), meant to stand in contrast to the far more common but less lethal "acute coronary syndrome" (ACS). AAS refers to the related processes of acute dissection (AD), intramural hematoma (IMH), and penetrating aortic ulcer (PAU). Although all studies are subject to ascertainment bias as some number of patients surely go undiagnosed, the best estimates of the incidence of aortic dissection derive from a handful of population-based analyses. Estimates from such studies put the incidence somewhere between 2 and 7/100,000. AD is roughly twice as common among men than women, and typically presenting among men in their late 40s to early 60s while women more often present in their 70s. IMH and PAU tend to occur in older patients, and more often affect the descending than the ascending thoracic aorta. AAS occur more frequently in the winter months than summer months, and more often in the morning than evening.
- Pathophysiology
  - AD is a mechanical failure of the aortic wall, and is associated with deterioration of the material properties of that structure. Histologically, this is reflected by medial degeneration—classically referred to as "cystic medial necrosis"—characterized by smooth muscle cell loss and elastin fragmentation. These changes may occur in the setting of some genetic disorders such as Marfan syndrome, Ehlers–Danlos syndrome, and other familial thoracic aortic syndromes, but are also normal consequences of aging. Factors that accelerate this process include hypertension and tobacco abuse, predisposing patients to aortic catastrophe. The inciting event is commonly held to be an intimal tear that permits entry of blood into the weakened media with distal and, in some cases, proximal propagation. In contrast, IMH is thought secondary to primary rupture of intramural vasa vasora. IMH can progress to AD, and some thinkers argue that all AD in fact begin as IMH. PAU may lead to IMH or AD.
- Clinical features
  - Although AD can be painless, most often it is associated with the acute onset of severe, tearing, migratory pain. These symptoms may be associated with unequal extremity blood pressures as well as a changing pulse exam (as the dissection evolves), either hypertension or hypotension, and/or a new murmur of aortic regurgitation. Although the presentation can be dramatic, with associated end-organ complications, such as syncope, cerebrovascular accident, anuria, or ischemic bowel, equally once the acute pain has passed the diagnosis may be subtle. Misdiagnosis of AD as ACS or other conditions such as pulmonary embolus is the rule not the exception. Accordingly, a high index of suspicion and low threshold to perform appropriate imaging studies are critical. The mortality rate associated with AD untreated is estimated at 1 to 2 percent per hour during the first 24 to 48 h and 75 percent at 2 weeks.
- Diagnostics
  - The diagnosis of dissection is critically dependent upon appropriate imaging studies. Electrocardiography (EKG) can be misleading, as compromise of the coronary ostia by the dissection may cause myocardial ischemia. Therefore, neither the presence nor absence of EKG changes rules out dissection. Plain chest radiography may demonstrate a widened mediastinum. Definitive diagnosis, however, is most often made by computed tomography (CT) scanning as it is widely available and is useful ruling out other conditions such as pulmonary embolism. Importantly, however, CT scans may be misinterpreted with AAS due to IMH missed or streak artifacts thought to represent a dissection "flap." The diagnosis can also be rapidly made using echocardiography, either transthoracic or transesophageal, if expert operators are available. Aortography is rarely used today except in the cardiac catheterization laboratory in instances in which the misdiagnosis of ACS was suspected. Magnetic

resonance imaging (MRI) is time-consuming and should only be used in unusual cases in which the diagnosis is evasive.

- Treatment
  - *Medical*: Aggressive anti-impulse pharmacotherapy is the first line of treatment for all AAS. β-Blockade is initiated first with a target heart rate of approximately 60 bpm, with vasodilator therapy (usually with nitroprusside) added to a target SBP of 110 to 120 mm Hg. Patients with type B pathology should continue on medical management unless their pain cannot be controlled or there is evidence of malperfusion or rupture. There is an emerging trend to treat these entities with endovascular stent grafts, although the evidence base for this in the absence of malperfusion is lacking as of this writing. Note that for practical purposes AD, IMH, and PAU are all treated similarly based on anatomic location ("type A" or "type B") and the above-mentioned complications.
  - *Surgical*: Currently, acute "type A" AD, IMH, and PAU are treated in most circumstances surgically. The standard of care is graft replacement of the ascending aorta. Primary treatment with "glues" is unproven and potentially harmful. The extent of distal repair should include the entry site if possible, and in most cases can be confined to hemiarch replacement; total arch replacement is rarely necessary in the acute setting. Most authorities feel the distal anastomosis should be performed "open" under circulatory arrest. Proximally, a regurgitant valve may be resuspended in many instances; however, complete root replacement should be performed if the sinuses are badly dissected or if connective tissue disease is suspected.
- Outcomes
  - The in-hospital mortality rate associated with surgical repair of "type A" dissection is approximately 25 percent, while that for medically treated "type B" dissection is closer to 10 percent. Late outcomes are disappointing, with survival after "type A" dissection at 1, 5, 10, and 15 years being 67, 55, 37, and 24 percent, respectively. Patients with type B dissections fared even less well, with survivals of 56, 48, 29, and 11 percent, respectively.

## BACKGROUND

Acute aortic dissection has been recognized as a clinical entity since the 18th century, with its most famous early victim King George II of England, the notoriously quarrelsome Hanoverian who fought bitterly both with his father and with his son, as well as Spain, France, and most of the rest of Europe during the Seven Years War. The latter conflict spread to the New World in the form of the French and Indian War, draining England's coffers the replenishment of which demanded heavy taxation of the American colonies and stimulated the birth of a nation. Although George II had no known history of high blood pressure, given this disposition, it seems reasonable to assume that hypertension may have played a role in predisposing him to this end on October 25, 1760, while "at stool." Antemortem diagnosis of dissection was first documented a century later by Swaine and Lantham in 1856, and successful surgical repair a century after that in 1955 by DeBakey, Cooley, and Creech.

Advances in surgical therapy have made diagnosis of more clinical relevance, and progress in imaging modalities has made diagnosis practical. Despite this, the majority of patients with acute dissection (AD) are initially misdiagnosed, most often as suffering from an acute coronary syndrome (ACS). Acknowledging this, Villacosta and Roman[1] coined the term "acute aortic syndrome" (AAS), a moniker referring to aortic causes of acute chest pain including AD, intramural hematoma (IMH), and penetrating aortic ulcer (PAU). The three entities are considered by many to lie along a spectrum of disease with similar pathogenesis, clinical features, and treatment algorithms. As AD is far more common—at least in the western world—we will focus on this entity making reference to the latter entities selectively and only as necessary.

## PATHOPHYSIOLOGY

Aortic dissection is associated with longstanding systemic hypertension, tobacco abuse, certain congenital anomalies including bicuspid aortic valve and coarctation of the aorta, as well as defined genetic syndromes including Ehlers–Danlos syndrome and Marfan syndrome. More recently, there is increasing appreciation for other familial thoracic aortic syndromes that may be secondary to mutations in TGF-β signaling or smooth muscle cell actin.[2] All of these result in medial degeneration. Histologically, this is characterized by elastin fragmentation, smooth muscle cell loss, and deposition of ground substance. This appearance was called "cystic medionecrosis" by Erdheim; however, the term has fallen from common usage as it does not accurately describe the pathologic process. Mechanically, the changes associated with medial degeneration result in increased wall stiffness and diminished elasticity.

Primary failure of the aortic wall occurs when the mechanical forces exceed the mechanical properties. It is increasingly apparent that measurement of aortic diameter alone is inadequate as a predictor of risk of dissection with aortic dissection quite clearly occurring at diameters less than 5 cm. Of course, structural failure occurs when wall stress, which is a product of aortic diameter and blood pressure, exceeds wall strength. Unfortunately there is currently

no clinically applicable methodology for assessing the material properties of the aortic wall. In this regard, knowledge of a family history of dissection or presence of a connective tissue disorder such as Marfan syndrome is probably our best clue to the structure of the aortic wall, and likely explains how this catastrophic event may occur even in the absence of significant aortic enlargement.

The century-old hypothesis for the genesis of aortic dissection is intimal disruption followed by propagation of an intimal flap within the media either proximally or distally. The minority view has held that all aortic dissections begin with intramural hemorrhage, which subsequently leads to rupture into the lumen and free communication between the vascular lumen and the propagating tear. Proponents of this view would argue that cases identified as AD have simply missed the IMH phase of the disease process. In support of this hypothesis is the higher frequency distribution of IMH relative to AD in the Far East, where computed tomography (CT) scanning is more frequently performed in evaluating chest pain possibly leading more frequently to capture of the process in its early stages. Although certain proof of the relative contribution of each mechanism to aortic dissection is certainly beyond reach, there is no question that patients with IMH can progress to dissection in at least some instances. The practical implication is that close attention should be paid to IMH and the potential for its malignant progression.

# CLINICAL FEATURES

## Epidemiology

Precise knowledge of the incidence of AD is complicated by incomplete ascertainment due to under diagnosis, which is a particularly vexing problem in this condition. Indeed, in a recent study at a tertiary referral center, over one-third of patients with AAS were misdiagnosed, most often as an ACS, with a clinically significant delay in appropriate treatment and, in most cases, frankly inappropriate treatment with antiplatelet agents (100 percent), anticoagulants (85 percent), or thrombolytics (12 percent).[3] The best possible estimates, however, come from population-based studies such as that reported from western Hungary, which identified AD in 2.9/100,000 inhabitants, with a male-to-female ratio of 1.55:1. Of note, AD was the initial clinical diagnosis in only 15 percent of cases, foreshadowing the findings of Hanson noted above. More recently, Clouse reported from Olmsted county, a small county in southeastern Minnesota principally served by the Mayo Clinic.[4] In this population, the estimated incidence of AD was 3.5/100,000 inhabitants, with 85 percent involving the ascending aorta. The results of a nationwide study in Sweden encompassing over 14,000 cases of thoracic aneurysm and dissection diagnosed between 1987 and 2002 identified an increasing incidence of disease over time, perhaps in part due to better diagnosis, to an incidence of 6.5/100,000 among men and 3.6/100,000 among women.

A great deal of data has been collected by the International Registry of Acute Dissection (IRAD) database. Their studies have confirmed an incidence in men roughly twice that in women, and a difference in age at presentation with women presenting later in life (mean age at presentation 66.7 ± 13.7 for women vs 60.3 ± 13.7 for men), and more frequently presenting late in the disease process with hypotension and tamponade.[5] This same database has demonstrated an increase in the incidence of dissection in the winter months (28.8 percent) versus the summer months (18.9 percent), and in the morning hours (37.4 percent between 06:00 and 12:00 vs 13.9 percent between 00:00 and 06:00).[6]

There are also some important epidemiologic differences between the "variant forms" of AAS, namely IMH and PAU, as compared with AD. In the western hemisphere, IMH is thought to represent approximately 5 percent of AAS.[7] Intriguingly, in the Far East IMH represents up to 50 percent of AAS.[8] Typically, the IMH patient is somewhat older (mean age 68.7 vs 61.7 in the IRAD database) and the disease more typically involves the descending thoracic aorta (60.3 percent vs 35.3 percent in IRAD). Malperfusion is distinctly uncommon as a consequence of IMH. Similarly, the typical PAU patient is also older, and in contrast to the typical AD patient, has extensive atherosclerotic disease.[9] Like IMH, PAU more often involves the descending thoracic aorta, and importantly, the ulcer is often in the mid or distal thoracic aorta.

## Clinical Presentation

Clinically, AD typically presents with sudden-onset, severe chest and/or back discomfort.[10] Characteristically the pain is experienced in the location of the dissection, which is to say those dissections involving the ascending aorta are most often associated with anterior chest pain while those involving the descending thoracic aorta are associated with back pain. The pain may migrate from front to back as the dissection progresses. Dissection can, however, be painless and some data from the IRAD suggest that the mortality rate associated with such dissections may even be higher than that with typical AD.[11] On physical examination, patients may present with either hypertension or hypotension. Differential blood pressure between extremities may be apparent. On occasion, the pulse exam will vary over time as flaps progress and malperfusion appears and disappears. A new murmur of aortic valvular insufficiency is almost diagnostic in association with an episode of severe, sudden pain.

The distinction between acute and chronic dissection is not always clear. The presence of a good history is of course helpful, although patients with chronic dissection may have chest pain of other etiology and, as noted above, AD may not be associated with pain. The presence of pleural or pericardial effusion on diagnostic imaging (see below) suggesting an acute process may be helpful if present. On some occasions, however, one may find oneself operating on an ascending aortic dissection still unsure if it is acute, chronic, or subacute.

## DIAGNOSTICS

Despite interest in the development of biomarkers for dissection, it remains a diagnosis almost entirely dependent upon advanced imaging modalities.[12] Electrocardiography is nonspecific, in so far as dissection may cause coronary insufficiency secondary to compromise of the coronary ostium by the false lumen. In the not-too-distant past, aortography was considered the "gold standard" and many surgeons would not operate without one. Over time, however, other modalities have superseded aortography such that the latter is relevant only when the patient is mistakenly taken to the cardiac catheterization laboratory for presumed ACS, or as part of the therapeutic intervention when placement of an endovascular stent graft is anticipated.

Most often today, a chest CT scan performed in the emergency room will be the first test used to rule out dissection, often one with contrast timed to rule out pulmonary embolism. In most instances, this is sufficient to make the diagnosis of dissection, although one can be fooled by streak artifacts that appear suspicious for a "flap" but are apparent only on one or two images and are associated with a normal diameter ascending aorta. In these instances, it is important to be sure that the apparent intimal flap is present in multiple images. It is also extraordinary to see AD without some degree of enlargement of the aorta itself. Conversely, an IMH or AD with thrombosis of the false lumen may be mistaken for a normal study if the lumen is smooth, regular, and of apparently normal diameter (Fig. 41-1). For this reason, one should look for medial displacement of intimal calcification as a tip-off to dissection or IMH (Fig. 41-2). Properly interpreted, however, the CT scan provides a wealth of information including the anatomy of the dissection at the level of the abdominal aorta and femoral vessels, which may be important if femoral cannulation for cardiopulmonary bypass is chosen (see below). Of course, CT scans can also be easily transported with a patient who is suspected of having dissection such that the surgeons at the receiving hospital may rapidly interpret those studies.

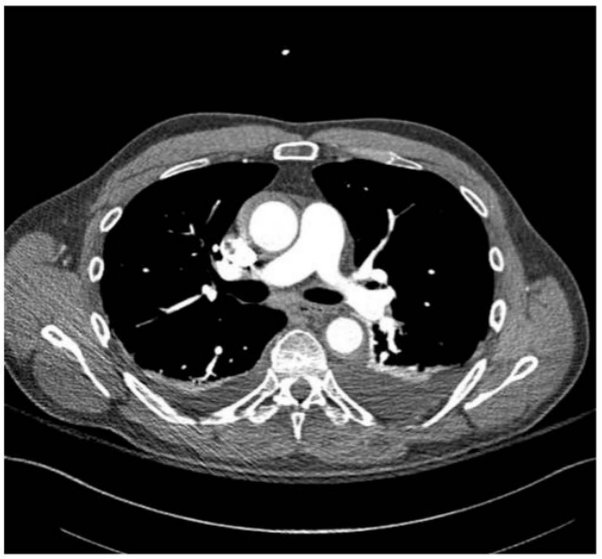

**FIGURE 41-1** Type I IMH with only mild enlargement of the ascending aorta. This can be mistaken for a normal study. Note the left pleural effusion and thickening of the wall of the descending thoracic aorta.

**FIGURE 41-2** Type I dissection with obvious flap in the ascending aorta. Note the medially displaced calcium in the descending thoracic aorta. In the presence of a completely thrombosed false lumen, this may be the only clue that one is seeing dissection versus intraluminal thrombus.

In current practice, a transthoracic or transesophageal echocardiogram is often obtained either as the primary diagnostic modality or as a confirmatory test either in the emergency room, or in our practice, in the operating room. As a primary test, this is perhaps the examination of choice provided skilled interpretation is available, as it imposes no contrast burden on a patient who may subsequently be going to the operating room for a lengthy procedure. Many surgeons are willing to take a patient to the operating room based solely on an echocardiogram demonstrating a mobile septum in the ascending aorta even without a CT scan. Conversely, however, if a CT scan is highly suspicious for type I or II/type A dissection, it is not our practice to insist on a confirmatory echocardiogram in the emergency room. We would rather obtain the transesophageal echocardiogram in the operating room accepting that it may actually rule out dissection than delay the patient's surgical care.

Magnetic resonance imaging (MRI) is employed rarely, and principally as a confirmatory test or as a means of serial follow-up.[12] MRI scanning is time-intensive and not as widely or expeditiously available. The scans themselves are,

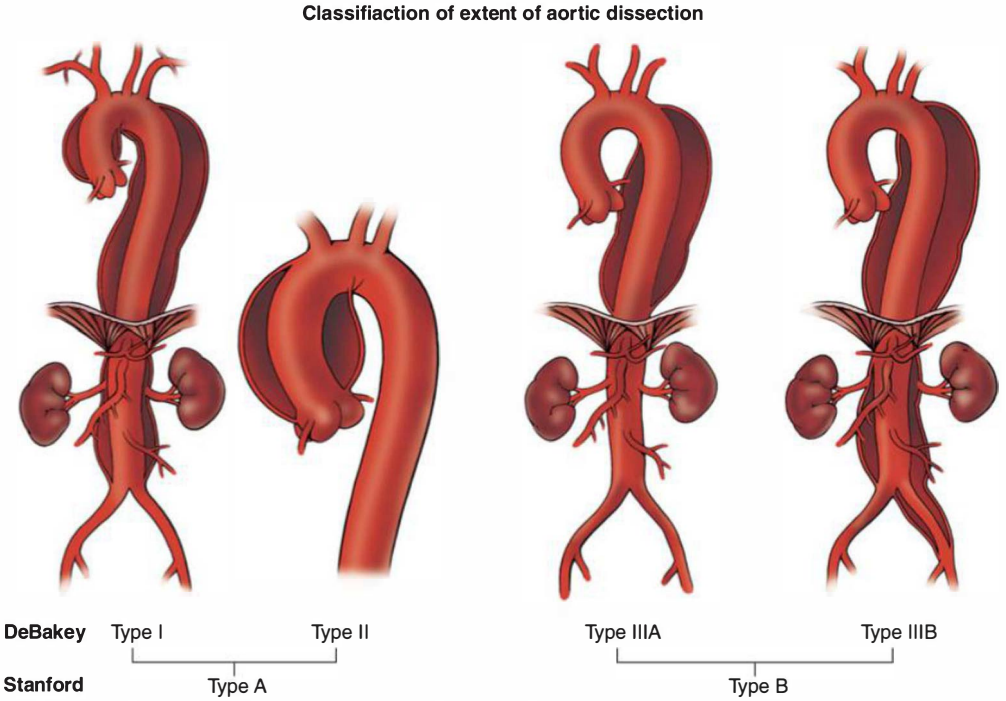

**FIGURE 41-3** DeBakey and Stanford classifications schemes for the extent of dissection.

at least in my opinion, more challenging for the surgeon to interpret as well.

On the basis of the imaging studies described, the AD should be classified according to extent as well as acuity. The two widely accepted classification schemes for acute aortic dissection are the DeBakey classification, which is more detailed but less often utilized because it is more complex, and the Stanford classification, which has been widely adopted particularly by our medical colleagues (Fig. 41-3). Dissections involving the ascending aorta may be DeBakey type 1 extending from the root through the arch into the descending thoracic and thoracoabdominal aorta or DeBakey type II, which are limited to the ascending aorta. The former are the most common, while the latter are the least common. Both are classified by the Stanford scheme as "type A" dissections, a moniker that can be remembered easily as they involve the ascending aorta. Dissections limited to the descending thoracic and thoracoabdominal aorta are classified as DeBakey II or Stanford B. Note that "B" and "III" rhyme, and that type B dissections involve the aorta in the back. It should be noted that a small number of DeBakey type III dissections may propagate somewhat proximally into the arch. Although there is some controversy, they are generally treated as type III dissections. Finally, while again there is some room for argument, dissections may be considered acute if the diagnosis is made within 48 to 72 h, subacute if within 14 days, and chronic if they have been present for over 2 weeks.

In the past, there has been controversy over the need for preoperative coronary angiography. Broadly speaking, however, the current consensus is that obtaining an angiogram is not necessary as concomitant occlusive coronary atherosclerosis is uncommon, and obtaining such studies delays surgical treatment. The potential exception to the rule would be the patient with known coronary disease, for example, status-post coronary artery bypass grafting.

## TREATMENT OPTIONS

The choice of treatment is determined by the location of the disease, the acuity of the presentation, and the presence or absence of complications such as malperfusion (Fig. 41-4).

### Medical Treatment

The first line of therapy for all ADs is anti-impulse therapy. Recognizing that deaths in dissection patients occurred secondary to extension of the dissection and rupture, not the initial tear, Myron Wheat and his colleagues sought to reduce the forces acting to promote these two complications with the aim of delaying surgery until the operation could be performed at lower risk. In a paper presented at the AATS meeting in 1965, they introduced the use of trimethaphan, reserpine, and guanethidine as anti-impulse and antihypertensive agents administered in the acute setting with the

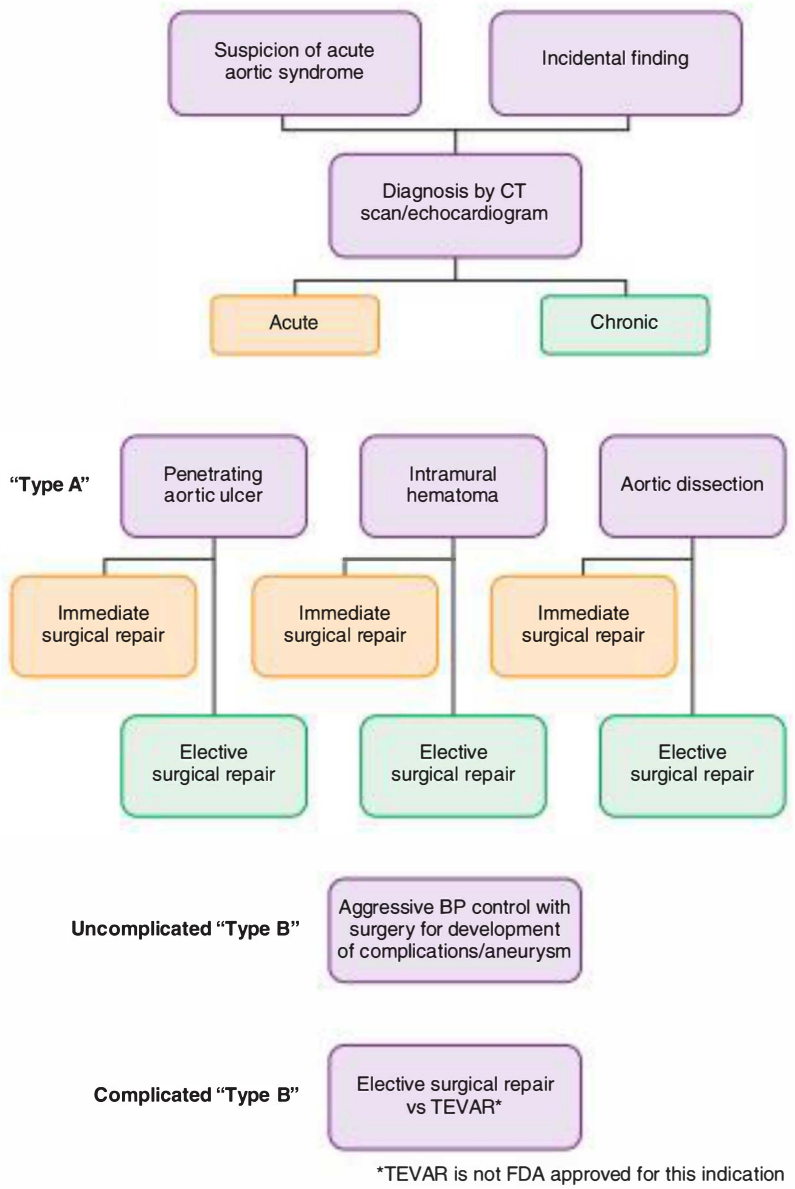

**FIGURE 41-4** Treatment algorithm for aortic dissection and its variant forms.

intention of carrying patients along into a chronic phase in which the risks of surgery would be less. In the current era, short-acting β-blockers such as esmolol are commonly combined with nitroprusside to accomplish these same aims. They should be instituted immediately upon diagnosis of AD, or even before if the clinical suspicion is high.

For uncomplicated acute type III/type B dissections, which is to say those without evidence of malperfusion, continued expansion, and unremitting pain, or rupture, continued medical therapy is preferred to surgical repair. Early studies demonstrated a three-fold higher hospital mortality associated with surgical intervention although it is certain that a greater number of patients with complicated dissections went to the operating room. In the current era, optimal medical management of type III/type B dissections is associated with an in-hospital mortality rate of 8.8 percent overall, and 7.4 percent for those in whom surgical therapy can be avoided.[13] Surgical therapy (endovascular or open) in the University of Texas series was required in 14.5 percent of patients. Overall, for uncomplicated dissections, the mortality rate was 1.2 percent. Initial medical management is, therefore, a well-established therapy for this condition.

FIGURE 41-5 Aneurysmal degeneration of the descending thoracic aorta following repair of type I dissection. Note that the area most prone to enlargement is the proximal portion.

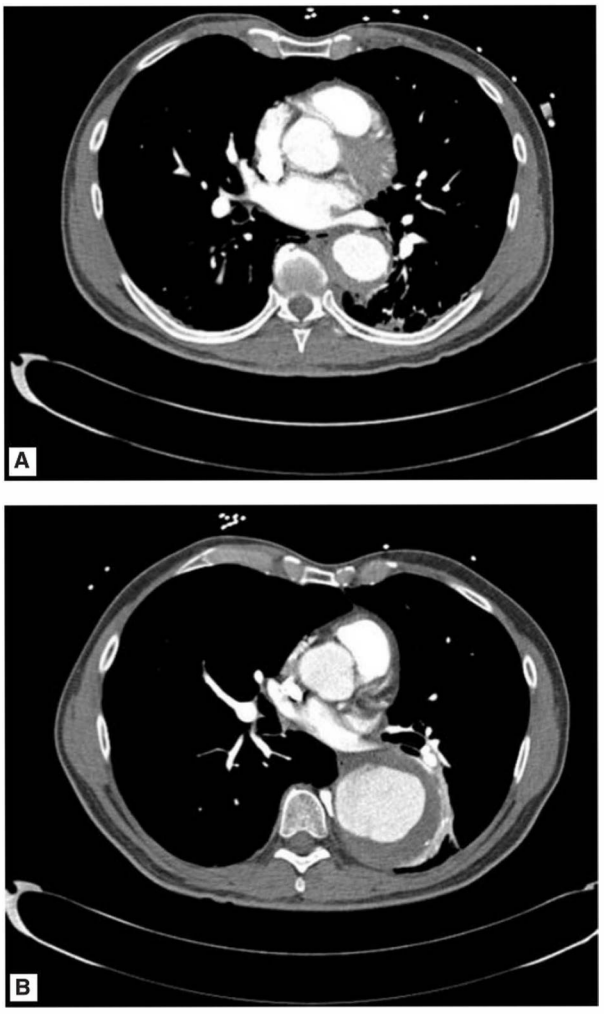

FIGURE 41-6 Aneurysmal degeneration of the descending thoracic aorta 2 years after acute IMH. **A.** Day 0. **B.** Two years.

Endovascular stent grafting as an alternative to medical therapy in type B dissection is increasingly accepted in the setting of complicated disease (see below), but hotly debated in the setting of uncomplicated disease as the outcomes with medical therapy are quite good. Of course, the unanswered question is how many uncomplicated dissections destined to become complicated could be stabilized with an endovascular stent. Long-term imaging surveillance is necessary to determine if aneurysmal dilatation occurs for which delayed surgery would be indicated (Fig. 41-5). This is true for IMH as well as AD (Fig. 41-6).

It should also be noted that ongoing medical therapy (as well as smoking cessation) is critically important in the chronic setting as well. Compulsive blood pressure control no doubt decreases the risk of subsequent dilatation of the dissected descending thoracic aorta. Although it is obviously difficult to demonstrate directly the impact of ongoing hypertension on the risk of reoperation, several studies have demonstrated an inverse relationship between the administration of β-blockers and reoperation. Aortic dissection should, therefore, be considered a chronic disease worthy of ongoing treatment and surveillance. All too many patients are "lost to follow-up" after successful surgical repair of an AD.

For acute type I and II/type A dissections, medical therapy is employed only as a bridge to the operating room. Except in unusual circumstances such as the very elderly or those with significant comorbidities, expeditious surgical therapy is indicated. Special circumstance include the patient with acute stroke or intestinal malperfusion who may be better

served with percutaneous reperfusion and a period of medical stabilization as advocated by Deeb and colleagues.[14] It must be noted, however, that even in the setting of acute stroke, some patients will do well with immediate surgical intervention. A second special circumstance is the patient who presents in a delayed fashion because of either a missed diagnosis or reluctance of the patient to seek medical care. Elefteriades has argued that such individuals can safely be held for semielective treatment after stabilization, full evaluation, and the availability of an elective "daytime" operating room.[15] It would be fair to say, however, that this position is controversial.

## Surgical and Endovascular Therapy

Broadly speaking, immediate surgical intervention is the accepted therapy for AD, IMH, or PAU involving the ascending aorta. The mortality rate associated with nonoperative therapy of dissection of the ascending aorta is 60 to 80 percent, while that for surgically treated patients is between 10 and 20 percent.[16] Of late there has been interest expressed, particularly by investigators in Korea, in managing IMH of the ascending aorta nonoperatively if the aortic diameter is <5 cm and the thickness of the hematoma is <1 cm; however, at the time of this writing, this should not be considered the standard of care.

Acute complicated type B dissections have traditionally been treated by open repair; however, the associated mortality rate may exceed 30 percent. Thoracic endografting is not FDA-approved for dissection; however, some surgeons are employing thoracic stent grafts in the setting of malperfusion as reperfusion can be accomplished quickly.[17] There is also interest in the long-term impact of restoring flow to the true lumen and excluding the false lumen in the upper descending thoracic aorta, which is the region most likely to dilate over time, even in the setting of an uncomplicated dissection. Again, however, this should not be considered the standard of care at this time.

### OPERATIVE PROCEDURES

***Type I and II/Type A Acute Dissections.*** The primary objective in the surgical management of a patient with AD is successful discharge from the hospital alive. This should temper enthusiasm to perform more extensive or elaborate procedures as are sometimes advocated in the literature including total arch replacement with the aim of reducing late reoperation or formal valve-sparing root replacements in the interest of avoiding long-term anticoagulation. This is not to say that, in expert hands, success cannot be achieved in these endeavors. Most ADs treated in the United States, however, are operated on by surgeons who seldom perform such procedures, even in elective circumstances. The primary responsibility of the surgeon facing a patient with an AD is to optimize the chance of the patient walking out of the hospital, and this includes an assessment of one's own comfort and confidence in performing the procedure necessarily to accomplish that goal. From this perspective, facing late reoperation after AD should be considered a good problem.

**Cannulation:** The traditional cannulation for acute aortic dissection is femoral arterial cannulation and venous return via the right atrium. Although alternate sites have been advocated, the femoral arterial approach continues to have vigorous proponents and it certainly must continue to be considered an acceptable approach.[18] Inspection of the preoperative CT scan will allow the surgeon to identify the preferred femoral artery that is perfused by the true lumen. Cannulation of the false lumen runs the risk of creating a malperfusion syndrome that did not exist, however, and for this reason some surgeons advocate bilateral radial arterial monitoring lines. Femoral cannulation also risks atheroembolism secondary to reversal of flow in the descending thoracic aorta, although this is relatively uncommon in the setting of AD as these patients usually have little in the way of atherosclerotic disease. An important exception is patients with penetrating atherosclerotic ulcers as the pathogenesis of their dissection.

An alternative site for arterial inflow that is gaining popularity is the axillary artery.[19] It is a bit more time-consuming to isolate the axillary than the femoral artery, and the axillary artery itself is a soft vessel not without the potential for complications. It too can be dissected, and cannulation of the axillary artery does not always guarantee adequate perfusion of both hemispheres of the brain. Nonetheless, this is certainly the popular trend as it facilitates selective antegrade perfusion (SAP) of head vessels during corporeal circulatory arrest. It is our preference to place a Dacron "chimney" graft on the vessel to minimize the risk of cannulation complications.

Most recently, there have been several groups advocating direct cannulation of the dissected ascending aorta.[20] Although this is a simple and expeditious technique, and should be kept in mind as a back-up, it is one that few surgeons in North America appear to have adopted as a preferred site.

**Perfusion strategy:** In addition to the site of cannulation for cardiopulmonary bypass (CPB), there is ongoing debate over the optimal perfusion strategy. In the early days, dissections were repaired under only mild or moderate hypothermia, with application of a crossclamp below the innominate artery. With the introduction of hypothermic arrest for the repair of degenerative aneurysmal disease, however, the same was applied as an option in the setting of AD. The clear disadvantage of longer pump times and more deranged clotting cascades with resultant bleeding on top of a condition for which perioperative bleeding was already an issue was in part overcome with the development of more hemostatic grafts, as well as systemic medications such as aminocaprioic acid and aprotinin. Indeed, the use of hypothermic circulatory arrest to permit performing an "open distal" anastomosis has become, in the view of many surgeons, the "standard of practice."[21] This approach permits a careful inspection of

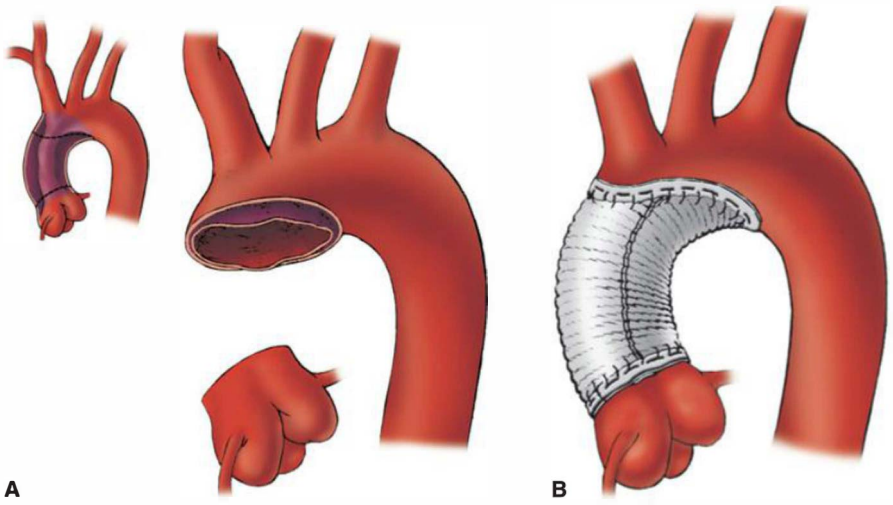

**FIGURE 41-7** Performing the repair under circulatory arrest permits careful inspection of the ascending aorta and arch, as well as latitude to perform an aggressive or conservative hemiarch replacement as per the judgment of the operating surgeon. **A.** At arrest. **B.** The desired end-result.

the anatomy and a more aggressive resection with construction of the distal anastomosis at the level of the pericardial reflection or beyond as a "hemiarch" replacement (Fig. 41-7). Some surgeons insist on resection of the segment of the aorta "with the entry tear" and argue that this can only be accomplished if the arch is inspected. The hope is that such a repair will reduce the risk of late reoperation. Although it is true that complete thrombosis of the distal false lumen appears to be associated with less late dilatation of the false lumen and superior late survival,[22] it is less clear that one can ensure this result by performing the distal anastomosis open. In point of fact, there are very often multiple "tears" in the intima, and the value of "resecting the tear" is unproven despite the reverence with which the "principle" is held. Consistent with this view, if one examines the data objectively, there is no hard evidence that performing an open distal anastomosis improved long-term outcomes.[23] For that matter, aortic dissection is a sufficiently uncommon event that it has been argued that the principles of evidence-based medicine cannot be applied.[24]

Of late, some surgeons have championed a middle-ground, with only moderate systemic hypothermia and SAP.[20] They argue that hemostasis is improved and that cerebral protection is equivalent. As long as one can be certain that corporeal arrest times will be short, this is likely a reasonable approach. If the distal anastomosis proves difficult, however, one might wish one had a bit more of a safety net of hypothermia.

If circulatory arrest is utilized, systemic cooling should be performed for a minimum of 30 min. The target nasopharyngeal temperature should be 18°C at which temperature circulatory arrest for periods of 30 min should be "safe." The arterial perfusate gradient should be maintained at 10° differential during cooling. This provides for even cooling of the brain. Data from the University of Pennsylvania suggest that cooling in excess of 45 min is probably not helpful and therefore in the absence of such monitoring, cooling for this period can be recommended as a safe practice.[25] At the end of the circulatory arrest episode, one should cannulate the graft itself and provide reperfusion in an antegrade fashion. Rewarming should be performed with an arterial-to-venous gradient again no greater than 10°C. Typically, it takes approximately twice as long to warm as to cool. Note that the duration of cooling may be guided by the intraoperative use of electroencephalography. Rewarming is continued in our practice to a temperature of 36°C. We are careful not to overwarm the patient as this can lead to neurologic dysfunction.

Finally, mention of adjunctive cerebral protection strategies is in order. Profound hypothermia was introduced as a simplification of complex branch perfusion strategies. Over time, however, interest grew in adjuncts or even substitutes, in particular retrograde cerebral perfusion (RCP) and, more recently, SAP. RCP was initially embraced by the aortic surgical community, but of late has fallen in use by only a few stalwart groups.[26] More often, SAP is utilized, particularly when the axillary artery is used for arterial inflow, as unilateral SAP requires only control of the origin of the brachiocephalic trunk.

**Extent of repair:** The extent of distal resection should be guided again by the primary aim—which is a live patient at the end of the procedure. Although it is our personal preference to perform a hemiarch replacement under circulatory arrest as we feel that beveling the distal anastomosis adds relatively little to the procedure if one is already committed to circulatory arrest, we have been reluctant to carry the logic further and conduct formal full arch replacement in the setting of AD (Fig. 41-8). This is not,

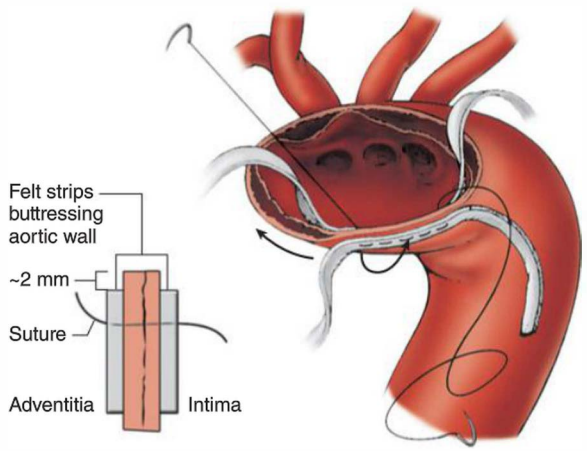

**FIGURE 41-8** Hemiarch replacement is conducted under profound hypothermia and circulatory arrest by first carefully constructing a "felt sandwich." This is a critical step, and if performed correctly assuring that both layers of the aorta are included for the full width of the strips of felt, ensures that both layers of the aorta will be included in the distal anastomosis. Once the reinforcement is complete, the graft-to-sandwich anastomosis can be conducted quickly with focus on including both layers of felt. This is a very hemostatic technique and requires no glues.

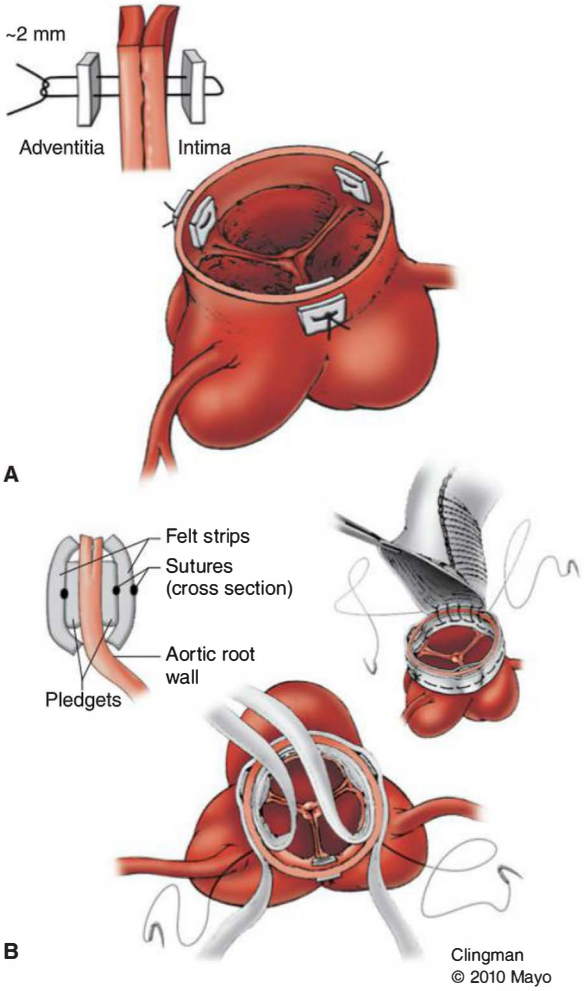

**FIGURE 41-9** The proximal anastomosis can often be performed at the sinotubular junction. **A**. If there is aortic regurgitation secondary to prolapse of a commissure, the commissures can be resuspended with pledgeted mattress sutures. **B**. I then create a proximal aortic sandwich analogous to the one created at the distal anastomosis. Care must be taken not to purse-string this reinforcement. (**B**: By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

however, a universally held position, and total arch replacement is strongly advocated by some, in particular among Japanese groups.[27] The argument is that in their hands total arch replacement adds little or no operative risk, and that is prevents late reoperation. The arch itself, however, does not usually dilate except in Marfan syndrome. Much more commonly, it is the proximal descending thoracic aorta that enlarges. Studies from the United States, however, have suggested that the distal extent of resection has no influence on reoperation.[28] The same logic applies to the current enthusiasm for inserting covered stent grafts distally in association with either arch replacement and a "frozen elephant trunk" or otherwise. Some early studies have suggested a not-inconsiderable incidence of paraplegia with these approaches, a complication that gives one particular pause as a consequence of a prophylactic procedure.

Similarly, the proximal extent of resection has not been shown to impact reoperation.[28] Quite often a valve resuspension can be performed if the dissection has disrupted a commissure causing aortic regurgitation. The commissure can be tacked up and reinforced with the proximal anastomosis (Fig. 41-9). Composite root replacement has been associated in some series with an increased operative risk. This is probably particularly true in practices where root replacement is not commonly performed. On the other hand, a young patient—and certainly a patient suspected of having Marfan syndrome—will probably do better in the long run with a formal root replacement. Patients with bicuspid aortic valves and ADs should likely have formal root replacement as well. The recent introduction of the David valve-sparing operations excites interest in this area as well. Again, our only admonition would be that a more complex procedure, if it adds operative risk, may not be in the best interest of the patient.

Root replacement may be with either a mechanical valve conduit or a biologic prosthesis. There are stentless Xenograft root prostheses available; however, not all hospitals will keep an inventory on hand and not all surgeons may be comfortable with implanting them. A simple alternative is to sew a Dacron graft to the sewing ring of a stented xenograft creating a "homemade" biologic

composite graft. The Dacron graft should be 3 to 5 mm larger than the nominal size of the stented xenograft. I typically run a 4-0 Prolene along the sewing ring of the xenograft through the Dacron graft as an over and over stitch. I then implant the root just as I would a mechanical valve conduit catching both the sewing ring of the valve and the Dacron graft with each valve stitch. The biologic conduit is then seated in place and coronary buttons reimplanted in the usual manner.

An appealing option, at least from a theoretical standpoint, is formal valve-sparing repair (VSRR) using either the David reimplantation technique[29] or the Yacoub remodeling technique.[30] Some surgical groups with extensive experience in VSRR have reported gratifying results; however, again it should be emphasized that survival of the patient is the highest priority. As most dissections in the United States are repaired by surgeons who perform aortic repair uncommonly, this is no condition in which to add the complexity of an aortic reconstruction that the surgeon also performs rarely. A middle ground is replacement of the noncoronary sinus alone as a "modified Yacoub" when the dissection has extended particularly into this sinus as is often the case (Fig. 41-10). This is certainly preferable to the use of glue (see below). When we perform a full root, we currently prefer the David reconstruction (Fig. 41-11).

In some instances, the coronary buttons themselves may be difficult to reimplant. This may be secondary to the fragility of the vessels themselves or scar tissue if the patient has undergone previous root surgery of any type. In these cases, a Cabrol coronary reconstruction can be lifesaving (Fig. 41-12). A 6- or 8-mm Dacron graft may be sewn end-to-end to the coronary buttons and then brought to the ascending graft as shown. If such a reconstruction is performed, one must be particularly attentive to the risk of kinking of the graft, particularly after weaning from bypass. A graft configuration that looks satisfactory prior to a weaning from bypass may not be ideal when the right ventricle is full and the right coronary button is brought higher and closer to the graft itself.

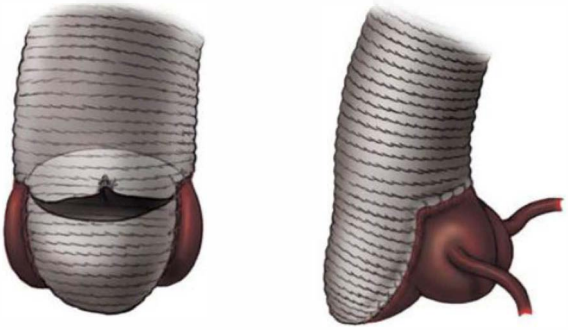

**FIGURE 41-10** If the noncoronary sinus is dissected, it can be replaced with a tongue of Dacron graft.

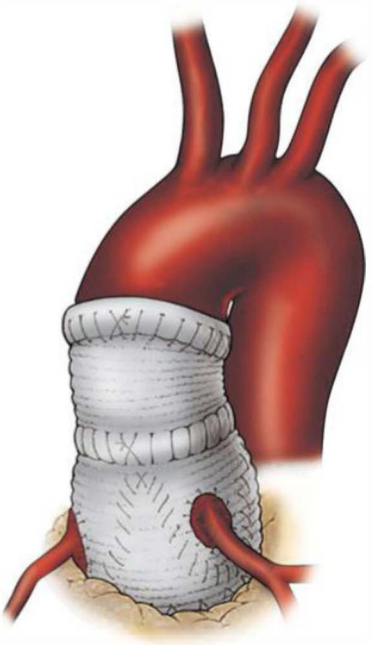

**FIGURE 41-11** When we perform a valve-sparing root reconstruction we currently prefer the David reconstruction. We use two grafts, the sinus portion being 6 mm larger than the tubular graft, with the latter sized to the annulus.

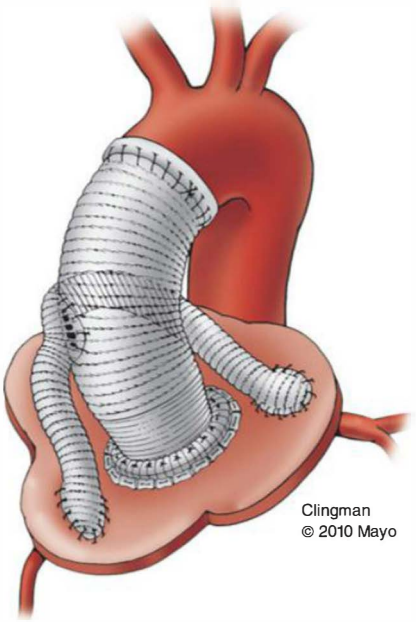

**FIGURE 41-12** If the coronary ostia are difficult to reimplant due to either fragility or scar from prior surgical interventions, they can be reconstructed with a 6-mm Dacron graft carefully anastomosed first to the ostia themselves and then to the main graft in a location that provides a comfortable lie. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

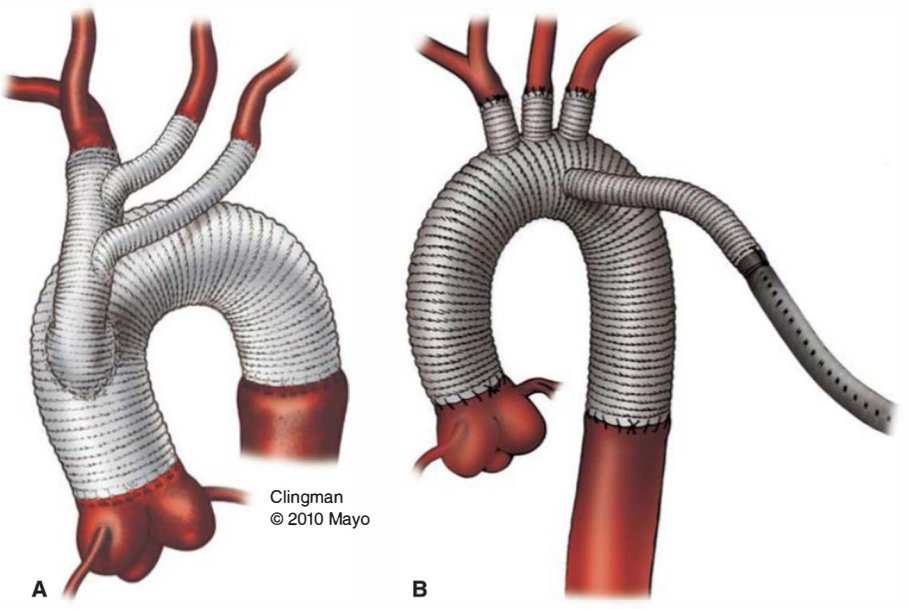

**FIGURE 41-13** If the arch needs to be reconstructed we currently prefer to do so with individual brachiocephalic anastomoses with either a trifurcated branch-graft (**A**) or branched arch graft (**B**). (**A**: By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Although there has recently been great enthusiasm for the use of adhesives in the setting of AD, it is not our practice to use these agents as we have been quite concerned about the potential for tissue necrosis secondary to their chemical make-up. We have seen any number of patients with pseudoaneurysms after repair of dissection who have, at reoperation, enormous quantities of biologic glue and associated obliteration of tissue planes and gray, fragile, fixed tissues.[31] Instead, we have used a time-honored and old-fashioned technique where a Teflon felt sandwich is created at both the proximal and the distal anastomoses. Strips of felt are placed inside and outside. We have not used a strip of felt as a "pseudomedia" as we have had the experience of reoperating on a patient from another institution with collapse of the intimal layer away from this pseudointima. Two layers of felt provide a very solid and hemostatic target for both the proximal and distal anastomoses. When we construct this sandwich, we run a horizontal mattress 4-0 Prolene suture being sure that the native tissue itself extends up above the limits of the sandwich. The greatest care is actually with creating this mattress stitch such that the subsequent anastomosis of the graft to the felt sandwich can be performed quickly being assured that if one has both layers of the felt, one also has both layers of the aorta.

***Type I and II/Type A Chronic Dissections.*** Chronic type A dissections should be repaired expeditiously, but not emergently. In the setting of chronic dissection, one has the same options available as in the treatment of chronic aneurysmal disease. Very frequently these patients will have significant aneurysmal dilatation of the arch as well as the ascending aorta. In this instance, we have adopted axillary cannulation and individual graft reconstruction of the brachiocephalic vessels as advocated by Kazui.[32] The individual brachiocephalic reconstructions are actually quicker to perform than a Carrel island patch and are also easier to repair if there is any bleeding from the anastomotic sites (Fig. 41-13). If there is an enlargement of the arch and upper descending thoracic aorta with relatively normal diameter aorta at the hiatus, we have adopted the transverse thoracosternotomy approach advocated by Kouchoukos[33] rather than the two-stage elephant trunk technique (Fig. 41-14). We prefer this even to the elephant trunk with subsequent endograft repair as it provides a secure conventional reconstruction and affords the ability to bevel the distal anastomosis, preserving as many intercostal vessels as possible. We have been concerned about the risk of paraplegia with extensive coverage of the descending thoracic aorta with endografts and see no advantage to the two-stage procedure even if the second stage is performed endovascularly.

***Type III/Type B Acute Dissections.*** In the setting of acute type B dissection, if operative intervention is required, we have preferred the use of circulatory arrest over left heart bypass. Provided there is not significant aortic regurgitation, this provides outstanding neurologic protection. It also affords one an excellent opportunity to perform a precise and secure proximal anastomosis to fragile tissues immediately distal to the left subclavian artery. Furthermore, in the setting of a type B dissection, all of the intercostal vessels are typically patent, which means that, under left heart bypass, all will be back-bleeding significantly. This can be dealt with by segmental clamping and quick hands, but a surprising amount of blood can be lost in a short period of time this way

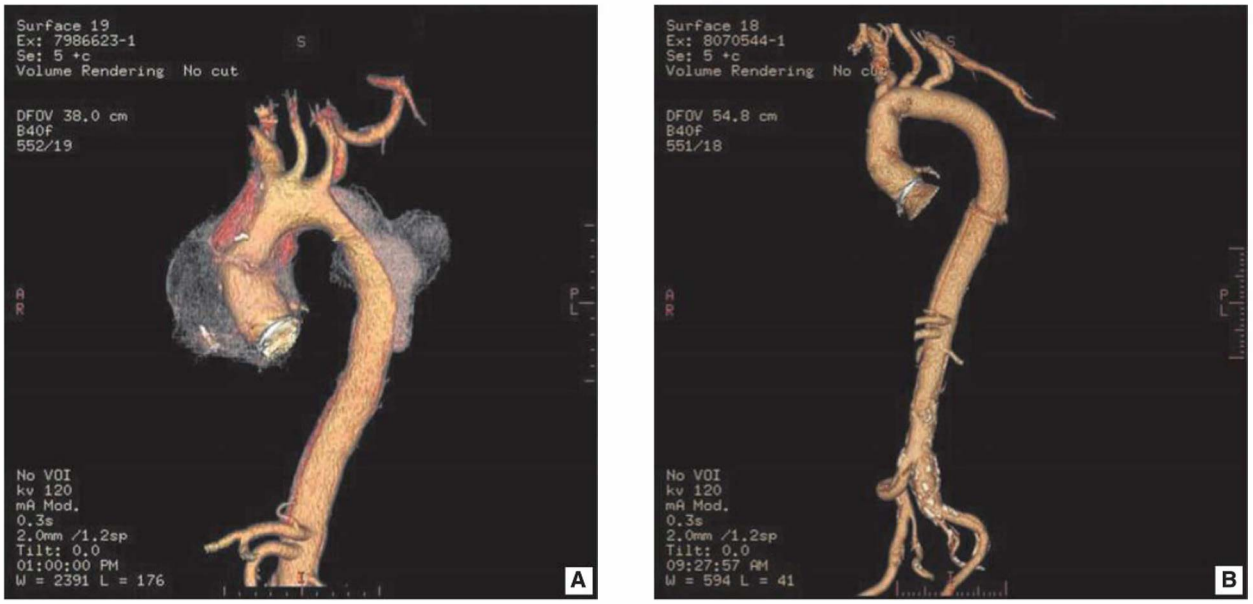

**FIGURE 41-14** A patient with chronic dissection and pseudoaneurysms at both proximal and distal anastomoses: preop (**A**) and postop (**B**). Glue had been used at both anastomoses.

and all shed blood is washed in the cell saver and the clotting factors are lost. Circulatory arrest also permits careful assessment of intercostal vessels to be reimplanted if that is your choice. It also permits careful assessment of the pathogenesis of the dissection, with inspection for the presence of a PAU. Recall that PAUs are more common in the distal thoracic aorta. Approaches that focus on replacement only of the proximal thoracic aorta may leave the PAU untreated.

With circulatory arrest, we have felt comfortable replacing the upper two-thirds of the descending thoracic aorta with a beveled anastomosis down to the diaphragm such that most of the thoracic aorta is extirpated. We believe that this may reduce the need for subsequent operative interventions as compared with replacement of only a very short segment immediately distal to the subclavian artery (Fig. 41-15).

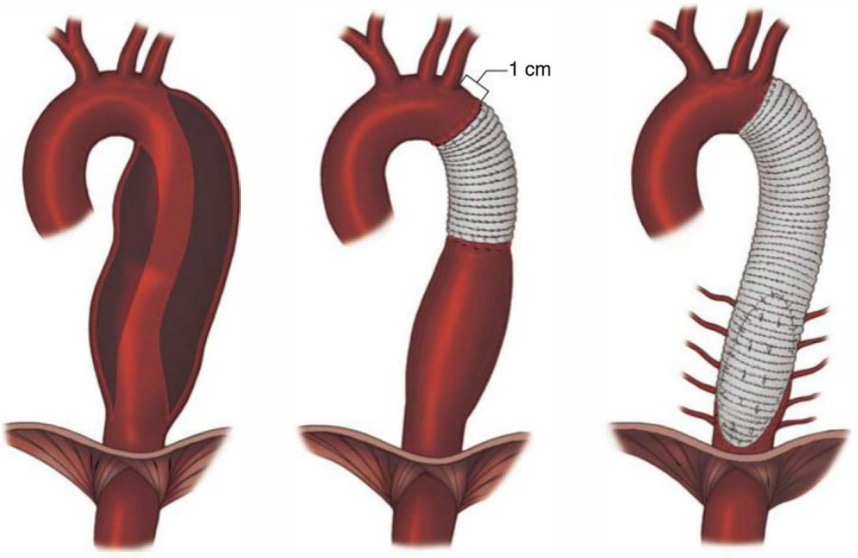

**FIGURE 41-15** When operating on an acutely dissected descending thoracic dissection under circulatory arrest, we have made an effort to extirpate most of the descending thoracic aorta rather than replacing only a short segment just distal to the subclavian artery. Beveling the distal anastomosis preserves the lower intercostal vessels and minimizes the risk of paraplegia.

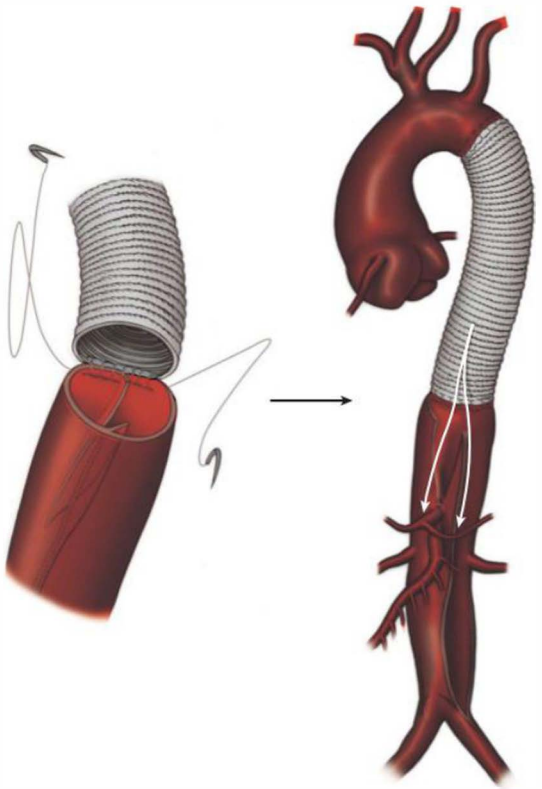

**FIGURE 41-16** Distal fenestration in repair of chronic dissection.

We typically cannulate for cardiopulmonary bypass in this setting either via a Dacron graft on the left axillary artery, via the femoral artery, or occasionally via the left ventricular apex with a femoral arterial inflow cannula. If the femoral artery has been used for inflow, after the proximal anastomosis is performed, we cannulate the graft and perfuse the upper body while we control the remaining intercostal vessels and perform the distal anastomosis at our leisure.

***Type III/Type B Chronic Dissections.*** The indications for surgical intervention on chronic type B dissections are based on aortic diameter and, very occasionally, on the basis of chronic malperfusion. In the setting of chronic type B dissections, we also prefer to use hypothermic circulatory arrest with the same approach as described above. We are always cautious to fenestrate the distal aorta rather than attempting to obliterate the false lumen (Fig. 41-16). Although left-heart bypass is advocated by some of the most prolific surgeons of the thoracoabdominal aorta[34] we were taught to use circulatory arrest.[35] Although the procedure itself takes longer given time to cool and rewarm, and the physiologic insult may be greater, we have been particularly pleased with the level of spinal cord protection afforded. Paraplegia is a devastating complication for the patient, family, and surgeon.

### POSTOPERATIVE CARE

The principles of postoperative care vary depending on the procedure performed. Among patients who have had repair of acute type I/A dissections, there should be aggressive control of hypertension both in the immediate postoperative interval and chronically. Rupture of the descending thoracic aorta after ascending repair occurs. In the chronic phase, there are some data to support the notion that long-term β-blockade and adequate blood pressure control reduce the risk of subsequent dilatation of the residual dissected aorta and accordingly the risk of subsequent operation.

The care of the patient following repair of the thoracic or thoracoabdominal aorta is, frankly, more complex. We have seen a significant incidence of delayed-onset paraplegia, most often associated with hypotension.[36] For this reason, among patients who have had extensive descending thoracic and thoracoabdominal repairs, we tend to have an approach of permissive hypertension aiming for a mean pressure of 85 to 90. In the months following repair, however, one could be more aggressive about blood pressure control. Follow-up scans should be performed at 6 months and then on an annual basis for several years, particularly for younger patients.

## OUTCOMES/PROGNOSIS

Patients surviving an AD require lifelong follow-up. Late survival of patients with dissection continues to be disappointingly below that of the normal population. It is likely that the long-term prognosis depends to a great extent on the adequacy of their follow-up, including aortic surveillance imaging, the rigor with which their blood pressure is controlled, and their access to subsequent surgical treatment should aneurysmal degeneration of the remaining dissected aorta occur. Approximately 30 percent of patients with dissection of the thoracoabdominal aorta—which includes both those with repaired type I/A dissection and those with chronic type III/B dissection—will ultimately come to surgical intervention. Most commonly it is the upper descending thoracic aorta that requires repair.

## AORTIC DISSECTION BOARD REVIEW QUESTIONS (CHAPTER 41)

1. Which of the following correctly describes a dissection that involves the ascending aorta?
   A. Stanford A and DeBakey II
   B. Stanford B and DeBakey I
   C. Stanford A and DeBakey III
   D. Stanford B and DeBakey III
   E. Stanford A and DeBakey IV

2. Which of the following is true regarding the presentation of aortic dissection?
   A. Occurs more commonly in women
   B. Presents at a younger age in men
   C. Develops more often during the summer months
   D. Occurs most often between the hours of midnight and 6 AM
   E. Penetrating ulcers more commonly involve the ascending aorta

3. The diagnostic imaging modality of choice for aortic dissection is:
   A. Aortography
   B. Echocardiography
   C. MRI
   D. CT
   E. Physical exam

4. Surgical intervention is indicated for which of the following?
   A. Acute type B IMH
   B. Acute type B dissection with diameter greater than 5 cm
   C. Chronic type B dissection with diameter less than 5 cm
   D. Acute type A penetrating ulcer
   E. Infrarenal dissection with extension into right iliac artery

5. Which of the following reduces the risk of reoperation after surgical repair of aortic dissection?
   A. Full root replacement
   B. Open distal anastomosis
   C. Total arch replacement
   D. β-Blocker therapy after operation
   E. Biologic glue reinforcement of proximal suture line

## ANSWERS

1. **Answer: C.** A Stanford type A dissection involves the ascending aorta. DeBakey type I and type II dissections also involve the ascending aorta, with the type I describing a dissection that extends into the descending aorta and the type II describing a dissection limited to the ascending aorta.
2. **Answer: B.** Aortic dissection is more common in men and occurs at a younger age in men. It is more common during the winter months and during the hours of 6 AM to noon. Penetrating ulcers most commonly involve the descending aorta.
3. **Answer: D.** Computed tomography is rapid, highly sensitive and specific, and gives detail on relevant anatomy.
4. **Answer: D.** IMH, PAU, and classic type A dissection are all indications for prompt surgical therapy. The remaining conditions only require surgery if there is associated complication, such as rupture or malperfusion.
5. **Answer: D.** Postoperative control of hypertension with β-blockade has been demonstrated to reduce the incidence of late dilation of the residual aorta, and therefore risk of reoperation. The listed intraoperative strategies have not been conclusively shown to reduce the risk of reoperation.

# Endovascular Repair of Thoracic Aortic Pathology

*Timothy J. George*
*James H. Black III*

**KEY CONCEPTS**

- Traditional open surgical repair of thoracic aortic disease is associated with significant morbidity and mortality.
- Endovascular stent-graft therapies have emerged as a minimally invasive approach to treating thoracic aortic pathologies.
- Stent-graft devices consist of membrane material mounted on an expandable metal stented framework.
- Although several imaging modalities have proved useful in planning and executing stent-graft deployment, computed tomography has emerged as the dominant imaging modality because of its wide availability, high resolution, and ability to obtain a variety of three-dimensional reconstructions of the thoracic and abdominal aorta.
- Endovascular stent grafts are deployed through sheaths placed in the common femoral or iliac artery. It is often useful to obtain vascular access through an extension conduit anastomosed to the common iliac artery via a retroperitoneal approach.
- There are four types of "endoleaks," or seepage of blood between the walls of the aorta and/or from graft material.
- Endovascular stent grafts have been used to repair aortic aneurysms, Stanford type B aortic dissections, penetrating atherosclerotic ulcers, and traumatic aortic transections. The results of these repairs are promising but still are accumulating.
- Complications of endovascular stent-graft repairs of the thoracic aorta include spinal cord ischemic injury, retrograde aortic dissection, and iliofemoral arterial injury.

## INTRODUCTION

Traditional open surgical repair of thoracic aortic disease continues to be associated with significant morbidity and mortality. Endovascular stent grafts have emerged as an exciting new technology to treat thoracic aortic pathologies. This minimally invasive approach decreases operative risk by minimizing aortic manipulation, avoiding large incisions and surgical hemorrhage, and circumventing the complications associated with cardiopulmonary bypass. This chapter presents the advantages and challenges of thoracic endovascular aortic repair (TEVAR) of the following pathologies of the thoracic aorta: aneurysm, dissection, penetrating atheromatous ulcers, intramural hematomas (IMHs), and traumatic lesions.

## COMPARATIVE RESULTS OF OPEN REPAIR

Before one begins a review of endovascular repair of thoracic aortic pathology, a review of the current state of open thoracic replacement is required. It is important to draw the clinical distinction between descending thoracic aortic (DTA) replacement and thoracoabdominal aortic (TAA) replacement. The current literature is replete with series of studies of TAA surgery,[1] but series detailing the results of lesser thoracic aortic operations are sparse. In DTA replacement, the duration of renal–visceral ischemia is minimal as the thoracic aortic anastomosis often can be accomplished with less than 30 min of aortic interruption. Indeed, if distal perfusion techniques are employed, renal–visceral ischemia

may be avoided completely. Thus, extrapolating the series detailing TAA replacement to the arena of DTA replacement overestimates the attendant risk of the pathologies now being addressed by endovascular means. Nonetheless, reviewing the literature of thoracic aortic replacement elucidates the risks both avoided (large cavitary incisions and blood loss) and assumed (paraplegia).

The largest series reporting results of DTA surgery for repair of degenerative aneurysms—not thoracoabdominal aneurysms (TAAs)—was published by Coselli and associates in 2004.[2] This series compared the results of surgical repair employing the clamp-and-sew technique with the results of distal aortic perfusion via a left heart bypass (LHB) circuit. Over a 15-year period, 387 patients underwent surgical repair by clamp-and-sew (341 patients; 88.1 percent) or distal perfusion (46 patients; 11.9 percent). Patients requiring profound circulatory arrest because of inability to cross-clamp the aorta (as a result of rupture, large size, or arch involvement) were excluded. Cerebrospinal fluid drainage (CSFD) was used in 24 patients (6.2 percent). The only statistically different preoperative characteristic of the two groups was that the presence of acute dissection was more often associated with the use of LHB ($p = 0.02$). All other variables were similar between the two groups. Intraoperative variables in the two groups were also similar in regard to the extent of the thoracic aorta replaced, the emergent presentation, and reattachment of intercostal arteries. The LHB patients required a longer cross-clamp time ($35.9 \pm 10.4$ min vs $26.9 \pm 9.9$ min, $p < 0.001$), more intraoperative blood products, and had more frequent proximal clamp placement between the left common carotid and the left subclavian than did those treated with clamp and sew (76 vs 54 percent, $p = 0.006$). Postoperative complications were encountered at similar rates regardless of technique. Thirty-day mortality data revealed 2 percent mortality in the LHB group and 2.9 percent mortality in the clamp-and-sew group ($p = 0.1$). Renal failure was noted in 7 percent of patients in both groups. Paraplegia rates were quite similar: a striking 4 percent in LHB patients and 2.3 percent in the clamp-and-sew group ($p = 0.3$). Although the authors hypothesized that patients in the LHB group had a higher risk profile and thus benefited from a subtle protective effect against paraplegia, further propensity analysis failed to support this conclusion. Thus, the application of LHB in patients undergoing thoracic aortic replacement for thoracic aneurysms may be left to the discretion of an experienced aortic surgeon.

Apart from distal perfusion techniques to prevent the dreaded complication of paraplegia, other strategies have been developed to protect the cord from interruption of spinal blood flow. Epidural cooling using an iced saline infusion into the intrathecal space is done to produce a temperature of 25°C to 28°C in the spinal canal, decreasing the neuronal energy requirement.[3] The flow rate into the epidural space may be limited by the measured cerebrospinal fluid (CSF) pressure (CSFP), as the target CSF perfusion pressure [mean arterial pressure (MAP)–CSFP] should be above 40 mm Hg.[4] Admirable paraplegia rates (6 percent) were reported from the Massachusetts General Hospital in its series of over 300 TAA repairs, a series that included a substantial number of high-risk patients many of whom presented acutely with rupture.[5] Commenting on that series, Cambria et al.[5] note that the application of local hypothermia avoids the need for systemic moderate hypothermia and the associated coagulopathy. Besides cooling, other mechanisms have been explored to lower spinal metabolism. Acher et al. reported the use of naloxone therapy and barbiturate-based anesthetics to decrease energy expenditure during the critical period of interruption of spinal blood flow.[6] In their series of 110 thoracic aortic repairs, an admirable 1.6 percent paraplegia rate was observed with this strategy, despite the deliberate oversewing of intercostal arteries in the critical thoracolumbar zone.

CSFD is perhaps the most studied and widely accepted strategy employed for the prevention of paraplegia in thoracic aortic surgery. Experimental data suggest that CSF pressure may rise with proximal aortic clamping and that reducing that pressure may improve spinal perfusion.[3] Thus, placement of a drainage catheter into the subarachnoid space to allow efflux of fluid during the operation and in the postoperative period may benefit the fragile circulation of the spinal cord. Generally, the fluid is able to drain when the CSF pressure exceeds 10 mm Hg as measured at the level of the spine. The beneficial effect of CSFD was demonstrated in a randomized trial comparing repair of type 1 and type 2 TAAs performed with or without CSFD.[7] A total of 145 patients underwent repair, with 76 receiving CSFD and the other 69 undergoing repair without CSFD. Aortic clamp times, LHB use, and the number of intercostal artery reattachments were similar between the groups. Nine patients (13.0 percent) in the control group had paraplegia or paraparesis; in contrast, only two patients in the CSFD group (2.6 percent) had deficits. Overall, CSFD delivered an 80 percent reduction in the risk of postoperative spinal ischemic complications after type 1 and type 2 TAATAA repairs. As CSFD catheter placement is not risk-free, it generally is accepted that CSFD is beneficial in operations in which aortic topography may mandate combined spinal and visceral ischemia, which includes most type 1 and all type 2 TAATAAs.

In addition to paraplegia, patients undergoing complex repairs of the thoracic aorta are at high risk of acute renal failure (ARF), an important contributor to postoperative morbidity and mortality. Unfortunately, the incidence of postoperative ARF is high and the consequences are severe. In a review of 234 consecutive repairs for TAATAAs or descending thoracic aortic aneurysms (DTAAs), Safi et al.[8] reported a 17.5 percent incidence of renal failure, with 15 percent requiring hemodialysis. Although 86 percent of survivors had resolution of their ARF within 30 days, renal failure was associated with a 49 percent mortality rate. Because of the high incidence and serious consequences of postoperative renal failure, many different interventions have been evaluated to reduce this complication. Although intraoperative treatment with mannitol, dopamine, calcium channel blockers, and various free radical scavengers are common, insufficient data exist to support their use. Indirect perfusion of the kidneys

via distal aortic perfusion has been utilized with success, with at least one study demonstrating a protective effect.[8] Several authors have reported results involving direct perfusion of the kidneys via cannulation of the renal ostia. Koksoy et al.[9] have demonstrated that in patients with type II TAATAAs, direct renal perfusion with hypothermic (4°C) lactated ringers resulted in a three-fold reduction in ARF compared with normothermic blood. Perfusion with cold blood, instead of cold crystalloid, does not offer additional benefit.[10]

## Johns Hopkins Approach to Open Thoracic Aortic Replacement

There are a number of approaches to the open replacement of the thoracic aorta. The authors' approach has been described in detail elsewhere[11] and is summarized here. Our operative approach begins with detailed preoperative planning utilizing high-quality imaging, computed tomography angiography (CTA) if possible, to evaluate the aorta for aortic atherosclerotic disease, dense calcifications, and aortic branch ostial disease to properly delineate the optimal sites for proximal cross-clamp, revascularization, and need for renal and/or visceral ostial endarterectomy.

For type I to III TAATAAs, CSFD, and LHB are employed. For type 4 TAATAAs, LHB and CSFD rarely are employed as no data exist to support their efficacy in these groups. The abdominal aorta is exposed via retroperitoneal dissection while the thoracic aorta is approached through a standard, posterolateral incision. The diaphragm is divided in a circumferential fashion to avoid injuring the phrenic nerve. LHB is instituted through the cannulation of the inferior pulmonary vein and an 8-mm Dacron chimney to the left common femoral artery. Distal perfusion is performed with moderate hypothermia (32°C) via a heat exchanger on a Bio-Medicus centrifugal pump. During the opening of the abdominal aorta, the renal artery ostia are flushed with 250 $cm^3$ of cold saline to aid in renal preservation.

To perform aortic reconstruction, the proximal descending aorta is isolated first via a proximal aortic clamp. This anastomosis is followed by subsequent sequential clamping of the aorta during each arterial anastomosis and reimplantation of intercostal, renal, and visceral arteries (Fig. 42-1).

# THORACIC AORTIC ENDOVASCULAR DEVICE OVERVIEW

First-generation stent grafts for repair of thoracic aortic pathology were bulky handmade devices that employed pressed Dacron material hand-sewn onto Gianturco stainless steel stents that necessitated large-diameter sheaths (26F) and stiff delivery systems, often requiring that conduits be sewn onto the iliac or abdominal aorta to accommodate the diameter of the delivery device. Newer-generation devices offer improved flexibility with small introducer systems. The US Food and Drug Administration (FDA) approved the first

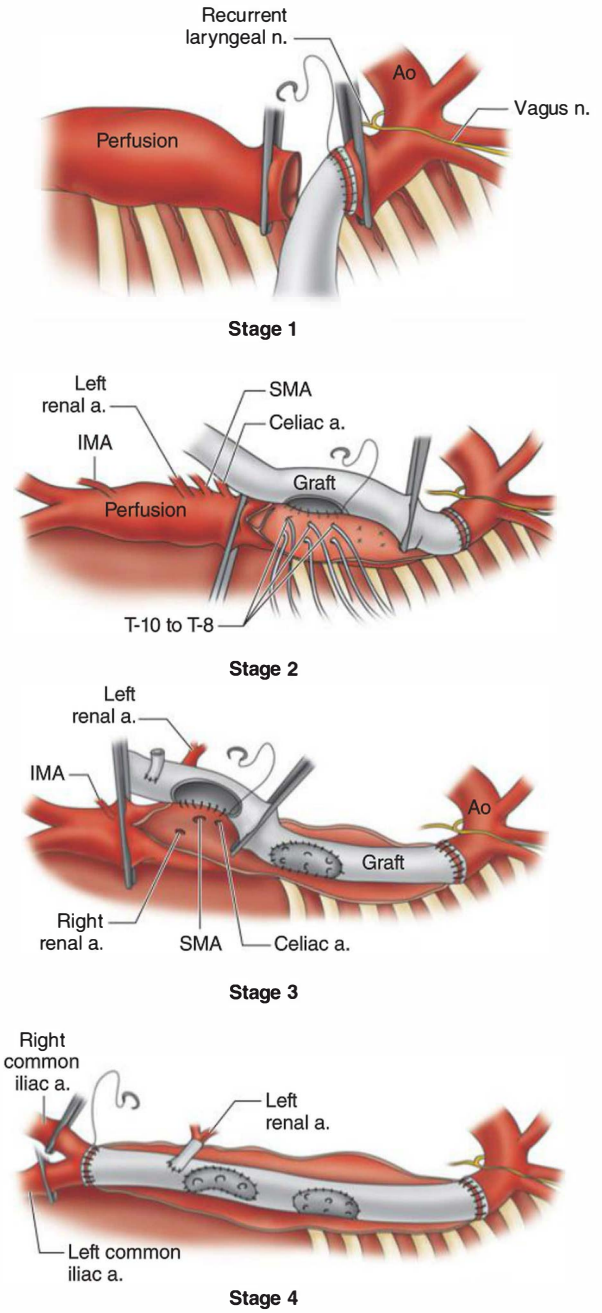

**FIGURE 42-1** Sequential stages of type II TAA repair. In Stage 1, the proximal anastomosis is performed while distal blood flow maintains renal and visceral perfusion. In Stage 2, the graft is clamped distal to the proximal anastomosis while the intercostals are reimplanted. In Stage 3, the graft is clamped distal to the intercostal patch and distal blood flow maintains pelvic perfusion during the renovisceral reconstruction. In Stage 4, the aortic bifurcation is reconstructed. (Reproduced with permission from Black JH 3rd. endovascular device for the treatment of degenerative thoracic aneurysms in late 2004.

There are currently three FDA-approved devices commercially available for endovascular repair of the thoracic aorta: the TAG endoprosthesis (W.L. Gore and Associates, Inc, Flagstaff, AZ), the Zenith TX2 TAA Endovascular Graft (Cook, Inc, Bloomington, IN), and the Talent Thoracic Stent Graft System (Medtronic Vascular, Santa Rosa, CA). All three devices, the TAG, the Zenith, and the Talent endoprostheses, consist of a series of self-expanding metal stents (either nitinol or stainless steel) affixed to tube grafts [made of polytetrafluoroethylene (PTFE), polyester, or woven graft, respectively]. Although the TAG device consists of single tube graft, the TX2 and the Talent are designed as two-piece systems with proximal and distal ends so that a combination of multiple proximal pieces and a distal piece can be utilized depending on the characteristics of the patient's individual aorta. In addition, the proximal component of the Talent device consists of several uncovered nitinol springs that allow the device to be deployed across a vessel (the left subclavian or left common carotid artery) without impeding blood flow. The treatable lengths and diameters for each device are listed in Table 42-1.

## DIAGNOSIS OF THORACIC AORTIC PATHOLOGY

A wide range of diagnostic tests are helpful in confirming suspected thoracic aortic pathology, including chest radiography, aortography, transthoracic echocardiography (TTE) or transesophageal echocardiography (TEE), magnetic resonance imaging (MRI), computed tomography (CT), and recently serum biomarkers. The benefits and limitations of each of those methods are reviewed below, along with their applicability to aneurysmal and dissection pathology.

### Plain Radiography

Classically, widening of the cardiac or aortic silhouette is cited as indicative of aortic disruption, along with pleural effusions and the displacement of aortic calcifications. Specifically, widening of the aortic silhouette was found in 60 to 90 percent of cases of aortic dissection by Hagan and coworkers in their review.[12] However, chest radiography has limited specificity and sensitivity.

### Aortography

This modality has both high sensitivity (86–88 percent) and high specificity (75–96 percent) for the diagnosis of aortic dissection.[13] Findings suggestive of dissection include distortion of the normal contrast column, flow reversal or stasis in a false channel, failure of major branches to fill, and aortic valvular regurgitation.[13] For the diagnosis of thoracic aortic aneurysm and treatment planning, aortography may improve the accuracy of length measurements of intended aortic seal zones (Fig. 42-2). In addition, aortography may be of benefit in defining aortoiliac occlusive disease, which may require angioplasty or a planned conduit for access for the stent-graft delivery. Nonetheless, enthusiasm for this modality is tempered by the potential for diagnostic confusion about malperfusion after pressurized injection, the risk of contrast nephropathy, the time delay to diagnosis, and the expense.

### Transthoracic Echocardiography and Transesophageal Echocardiography

TTE has a sensitivity of 35 to 80 percent and a specificity of 40 to 95 percent for the detection of aortic dissection,[14] whereas the sensitivity of TEE is reportedly as high as 98 percent, with 63 to 96 percent specificity.[15] TTE may be limited technically by body habitus, emphysema, and narrow intercostal spaces. Although TEE is more invasive, it expands the diagnostic ability of echocardiography, potentially demonstrating entry tear sites, flow within the false lumen, involvement of the arch or coronary arteries, degrees of aortic valvular regurgitation, and pericardial effusions. However, one must be mindful of its limitations in imaging the anatomic blind spot in the distal ascending aorta and arch secondary to the air-filled trachea and left mainstem bronchus. In addition, TEE cannot image aortic pathologies past the diaphragm.

### Magnetic Resonance Imaging

MRI has unparalleled sensitivity and specificity for detecting aortic pathology, for instance, 95 to 100 percent for

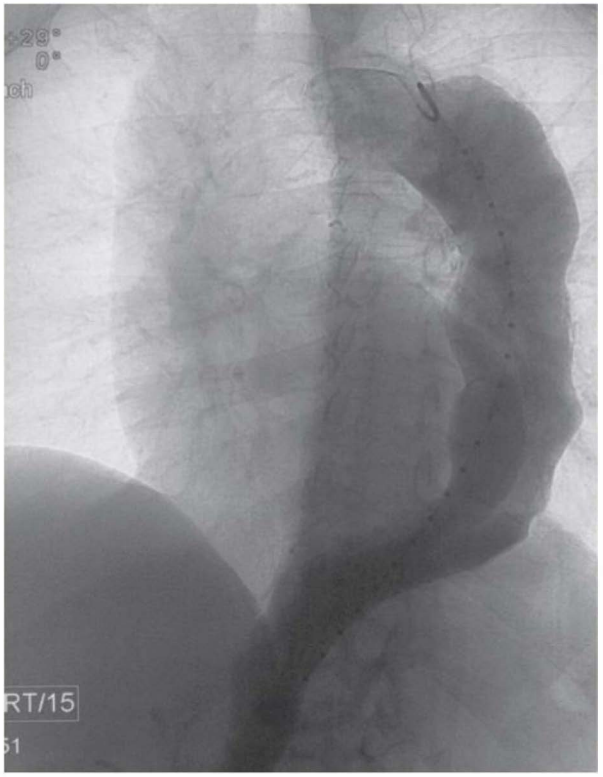

FIGURE 42-2 Angiography is a vital adjunct to preprocedural planning.

dissection.[16] Recent advances in three-dimensional (3-D) reconstruction of gadolinium-enhanced magnetic resonance angiography (MRA) are beneficial in planning thoracic aortic stent-graft treatment in patients whose comorbidity profile includes renal insufficiency. However, this enthusiasm must be tempered by the realities of long examination times, inability to monitor critically ill patients, expense, and lack of immediate availability. Moreover, MRI is contraindicated for patients with implants or pacemakers.

## Computed Tomography

CT offers multiple benefits and is the most commonly used diagnostic test in patients with suspected aortic pathology. Readily available, CT scanning carries a sensitivity of 83 to 95 percent with a specificity of 87 to 100 percent for the detection of acute aortic dissection.[17] This modality can be particularly helpful in examination of the true versus the false lumen. A slit-like compressed true lumen should heighten suspicion for branch vessel compromise and malperfusion syndrome substantially (Fig. 42-3). In addition, CTA has evolved so that multiple reconstructions can be created from the source axial images, rendering this diagnostic modality vital for preoperative planning.

## Serum Biomarkers

Serum biomarkers, particularly D-dimer, represent an emerging diagnostic tool for detecting aortic dissection, particularly for screening patients with chest pain in whom high-quality, axial imaging would be prohibitively expensive. When the aortic media tears, the extrinsic pathway is triggered resulting in the cross-linking of fibrin. D-dimer is a degradation product of this cross-linking reaction and thus represents a potential biomarker of aortic dissection. A cutoff value of <500 ng/mL can be used to rule out aortic dissection, yielding a negative likelihood ratio of 0.07 and a negative predictive value of 95 percent.[18] However, up to 18 percent of patients with confirmed aortic dissection will not have a D-dimer level greater than 400 ng/mL[19] likely secondary to the variability of serum levels based on the time since dissection. Thus it is currently most useful to rule out patients who are considered low risk.

# IMAGING FOR PLANNING THERAPY

Endovascular repair of thoracic aortic pathology requires facility with the interpretation of axial imaging such as CTA and MRA to inspect aortic topography for device insertion and fixation. In addition, planning of thoracic aortic endografting may be aided by conventional diagnostic arteriography, using both subtracted and unsubtracted techniques, especially when 3-D imaging cannot be obtained from available axial data. A key tenet of thoracic aortic endovascular repair is the understanding that device selection and operative planning should be confirmed and verified to the greatest extent possible preoperatively as errors in device measurements often translate into immediate treatment failures.

Insertion planning for endovascular devices requires a thorough understanding of the aortic diameters at the proximal and distal sealing sites as measured from outer wall to outer wall. The indications and sizing guidelines for the current FDA-approved devices are summarized in Table 42-1.

Oversizing the graft too aggressively may place undue forces on the aortic endograft and result in migration or collapse of the entire graft.[20] The length of proximal fixation should be more than 20 mm (or 25 mm in the case of the Zenith device) with an acceptable aortic diameter throughout this seal zone. If an adequate proximal fixation length is not immediately obtainable, the left subclavian artery (LSA) can be crossed and excluded with little consequence to the patient (mean left arm pressure decreased, with few symptoms); if the patient has a prior left internal mammary-to-coronary bypass, a left-carotid-to-left-subclavian bypass is required to maintain coronary circulation before coverage. Further encroachment into the arch generally requires salvage of the left common carotid circulation by a prior carotid–carotid bypass. If excessive tortuosity is encountered in either fixation zone, a longer seal length of up to 30 mm may be needed to prevent blood from escaping around the

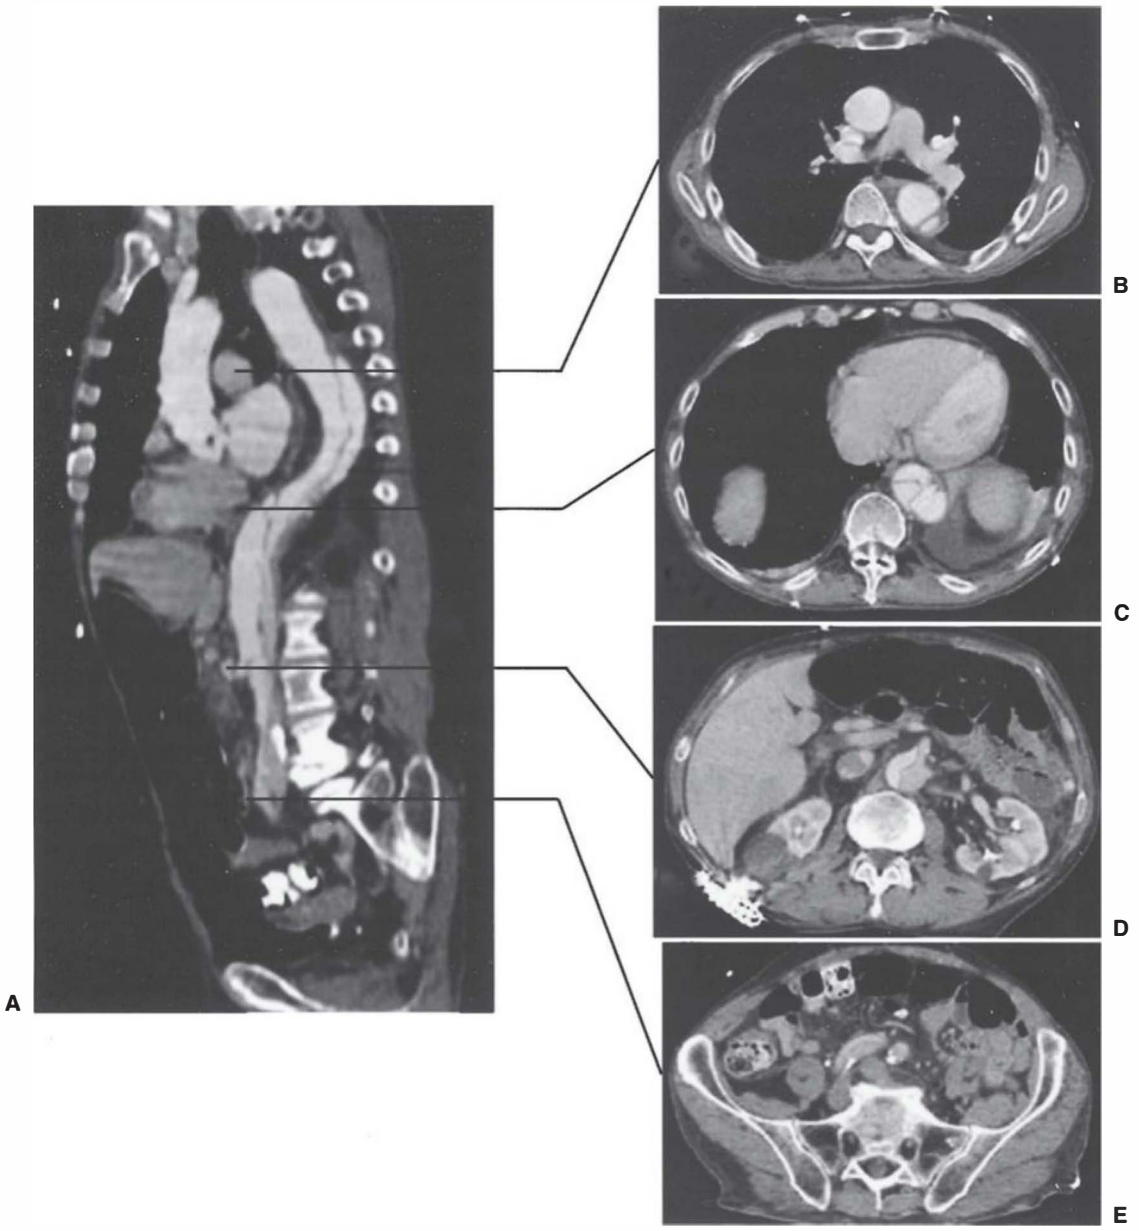

**FIGURE 42-3** Three-dimensional helical computed tomography has a sensitivity of 83 to 95 percent and a specificity of 87 to 100 percent for the detection of acute aortic dissection.

ends of the stent (type 1 endoleak). When multiple devices are required to cover long lengths of aortic pathology, each piece should be made to overlap 3 to 5 cm with the neighboring endograft. The distal aortic seal zone is usually cephalad to the celiac axis.

A common theme in complications of aortic endografting is the occurrence of damage to access vessels such as the common femoral and iliac arteries. Therefore, if the measured diameter of an intended access vessel is demonstrated to be less than 8 mm, serious consideration should be given to a surgical conduit. To create a conduit, 10-mm Dacron conduits generally are anastomosed to the common iliac or abdominal aorta via a miniflank incision with retroperitoneal exposure of the vessel. In particular, severe calcification of an access vessel may increase the risk of tear, perforation, dissection, or frank rupture. It is not uncommon for such iatrogenic injuries to become obvious when the device sheath is being withdrawn, not at the time of sheath insertion. As the device sheath is removed, the obturation of the injury is relieved and hemorrhage ensues.

## IMPLANTATION TECHNIQUE

The procedure of aortic endografting for thoracic aortic pathologies should be performed in an operating room with a high-resolution digital imaging system and a radiolucent table. The choice of anesthetic generally is based on preoperative cardiac risk stratification and may include local, epidural, and general anesthesia. The application of CSF drainage should be considered when coverage of the entire thoracic aorta is planned or if a prior abdominal aortic aneurysm (AAA) repair has been performed. Grafts are inserted via cutdown on the intended access vessel, most commonly the right common femoral artery. After this surgical exposure, systemic anticoagulation is achieved, using heparin to maintain an activated clotting time (ACT) greater than 250 s. An angiographic catheter is inserted percutaneously via the opposite common femoral artery or brachial artery to the level of the aortic arch. Using digital subtraction angiography, aortic arch or thoracic aortic angiography is performed to determine the approximate positioning of the endoprosthesis. To view the landing areas in the arch, it often is necessary to view the arch with a 60-to-90 degree left anterior oblique (LAO) projection. To view the distal seal zone, a similar steep, nearly lateral projection best depicts the level of the celiac axis (Fig. 42-4).

To minimize manipulation, particularly in the arch, the final diagnostic studies before deployment should be performed with the device nearly in place; the stiffness of the wires and delivery systems may alter the course of the aortic arch and affect the landmarks being used to mark the proximal limits of deployment. "Road-mapping" techniques or "fluoro-fade" may improve operator accuracy in proximal fixation. Maneuvers to minimize stroke include flushing of all air from the device sheaths and lumens carefully. Also, manipulation of stiff wires into and from the arch should be done carefully under fluoroscopic guidance. After deployment, fixation should be improved by using a large-diameter compliant occlusion balloon to maximize apposition of the stent graft to the aortic seal zones and regions of device overlap in a distal-to-proximal order (Fig. 42-5). The access sheath is removed carefully, with attention paid to MAP as an early indicator of hemorrhage from iatrogenic insertion injury. If a tear in a vessel is suspected, the sheath can be reintroduced to obturate the injury. If the sheath will not pass, an occlusion balloon can be passed proximal to the injury and inflated to achieve vascular control. Frank transections usually require a flank incision and reconstruction, whereas small tears or dissections often are salvaged by endovascular stent placement without conversion.

**FIGURE 42-4** Distal aortic projection with a 68 degree left anterior oblique view often is required for proper visualization of the celiac axis for sizing. The figure shows a larger graduated device posterior to the pigtail catheter.

**FIGURE 42-5** Deployed stent graft.

### Johns Hopkins Approach to Thoracic Aortic Stent Grafting

In light of the preponderance of iatrogenic access injuries, the authors aggressively apply retroperitoneal conduits via a flank incision. Most patients undergo general anesthesia both for flexibility of access approach and to avoid patient movement at critical imaging moments. The operations are performed in an endovascular operating room with a ceiling-mounted imaging device.

## THORACIC ENDOVASCULAR AORTIC REPAIR OF ANEURYSMS

With an estimated incidence of 6 to 10 cases/100,000 person-years, a thoracic aortic aneurysm carries a substantial risk of mortality. Coady and associates[21] found a 27.9 percent total incidence of rupture or dissection for DTAAs larger than 6.0 cm. The long-term survival of patients with untreated DTAAs at 1 and 5 years was 88 and 6 percent, respectively.[21] As with AAAs, the yearly risk of rupture or dissection for DTAAs has been found to correlate with size: 2 percent for small aneurysms, 3 percent for aneurysms 5.0 to 5.9 cm, and 6 percent for those equal to or larger than 6.0 cm. The risk of death along with rupture and dissection increases markedly at 6.0 cm: 6.5 percent yearly for aneurysms 5.0 to 5.9 cm but 14.1 percent for those equal to or greater than 6.0 cm.[22]

The results of TEVAR in DTAAs are summarized in Table 42-2.[23–26] In the table, endoleak refers to the seepage of blood between the previously sealed walls of the aorta and graft material. Endoleaks are divided into four types: Type I endoleaks occur as a consequence of a poor seal between the aorta and[23] the proximal or distal attachment sites of the graft, type II endoleaks are characterized by back bleeding from branch vessels, type III leaks involve blood excursion between multiple components of grafts, and type IV endoleaks occur when blood transgresses from the lumen through the material of the graft itself.

The use of stent grafts to treat DTAAs was pioneered by Dake et al. in 1994.[25] Although endovascular repair previously had been described for AAAs, subclavian artery aneurysms, arteriovenous fistulas, and femoral occlusive disease, this group from Stanford extended the technology to the thoracic aorta. Their series of 13 patients had 100 percent technical success and no mortality nor paraplegia. The authors reported that two patients had "small patent proximal tracts communicating with the aneurysm" that resolved over the ensuing months and that two more patients required a second procedure to eliminate "residual filling from either a proximal communication or a distal communication," presumably type I endoleaks (30.8 percent). In light of those promising early results, the authors advocated endovascular treatment for highly selected patients.

The first long-term outcomes were reported by Makaroun et al.[26] who reported the midterm follow-up results of the Gore TAG trial. This trial compared 191 patients who underwent endovascular repair of DTAAs with the TAG device (51 patients were enrolled after redesign of the endograft device) to 94 patients who underwent traditional, open repair. At 5-year follow-up, patients undergoing endovascular treatment had a decreased rate of aneurysm-related mortality (2.8 vs 11.7 percent, $p = 0.008$) and a similar rate of all-cause mortality (68 vs 67 percent, $p = 0.433$). TEVAR was associated with a lower incidence of major adverse events in the first postoperative year (42 vs 77 percent, $p < 0.001$) and these patients were less likely to have bleeding, pulmonary, renal, neurologic, or wound complications; however, TEVAR patients were more likely to have vascular complications at 5 years. Endoleaks, predominantly type I, occurred in 21 percent of patients who underwent endovascular surgery, and 3.6 percent patients in the endovascular group required postoperative reintervention. Only one patient required conversion to an open procedure 73 days after endovascular treatment secondary to the detection of an aortoesophageal fistula. At 5 years, the aneurysmal sac size had decreased in 50 percent of patients and increased in only 19 percent. In addition, at 5 years, there were no ruptures, no stent-graft collapse, and only one incident of significant stent migration. These encouraging long-term results lead the authors to conclude that TAG thoracic endografting is not only a safe and effective method of repairing DTAAs, but superior to open repair in terms of aneurysm-related morality.

Although initial trials were performed with the TAG device, additional trials have since followed utilizing other devices. Matsumura et al.[23] evaluated the Zenith TX2 device, comparing 160 patients who underwent endovascular repair

**TABLE 42-2: Results of Endovascular Repair of Thoracic Aortic Aneurysms**

| | Dake (1994) | Czerny (2004) | Makaroun (2008) | Matsumura (2008) |
|---|---|---|---|---|
| Technical success | 100% | 94.4% | 98% | 98.8% |
| 30-day mortality | 0% | 3.7% | 2.1% | 1.9% |
| Complication rate | 7.7% | 1.9% | 57.9% | 41.9% |
| Paraplegia | 0% | 0% | NR | 1.25% |
| Endoleak | 30.8% | 28.9% | 21% | 13% |
| Mean follow-up | 11.6 months | 38 months | 37 months | 12 months |
| Long-term survival | 100% | 92.6% | 68% | 91.6% |

of their DTAA to 70 patients who underwent traditional, open replacement. Although the 30-day and 1-year survival rates were similar between the endovascular and open groups, patients undergoing TEVAR had fewer cardiovascular, pulmonary, and vascular adverse events (41.9 vs 68.9 percent, $p < 0.01$). Endovascular repairs were complicated by a similar rate of reintervention as those undergoing open repair. In addition, at 1 year, there were no aneurysm ruptures, a 3.9 percent incidence of endoleaks, and a 2.8 percent incidence of graft migration. This study demonstrated that endovascular repair with the TX2 device is a safer and equally effective alternative to open surgical repair for DTAAs.

The overwhelming majority of large studies that have evaluated endovascular repair of thoracic aneurysms have examined the outcomes of elective repairs. Recently, however, Jonker et al.[27] conducted a meta-analysis of endovascular repair of ruptured DTAAs. This study examined 224 patients, 64 percent treated with endovascular repair and 36 percent with open repair. TEVAR was associated with decreased 30-day mortality (19 vs 33 percent, $p = 0.016$) and a decreased incidence of perioperative myocardial infarction. Notably, four patients treated with TEVAR who were alive at 30 days died because of exsanguination due to rupture of the stented aneurysm or the adjacent aortic segment. Another patient died due to an aortobronchial fistula. In contrast, there were no aneurysm-related deaths in the open group during follow-up. Although TEVAR of ruptured DTAAs is associated with a lower 30-day mortality compared with open repair, it is also associated with more aneurysm-related deaths on long term follow-up.

With an increasing focus on the costs associated with health care delivery, increased attention is being paid not only to the effectiveness of novel therapies such as endovascular repair of DTAAs, but also to their cost-effectiveness. Although several studies including those mentioned above demonstrate improved survival and shorter length of stay for TEVAR versus open repair, few studies have examined the differences in cost. Recently, Arnaoutakis et al.[28] reported that while TEVAR demonstrates improved mortality and shorter intensive care unit (ICU) and overall length of stay, it is associated with similar total charges despite high-device costs (US $61, 909 vs US $64, 531, $p = 0.40$).

## THORACIC ENDOVASCULAR AORTIC REPAIR OF DISSECTIONS

Acute aortic dissection is the most common catastrophe of the aorta, with an annual incidence of 5 to 30 cases/million people/year.[12] Age, hypertension, and structural abnormalities of the aortic wall contribute to the actual incidence within a population.[12] A male:female ratio of 5:1 is consistent across many series,[29] the incidence of dissection peaks at 50 to 60 years of age for type A and at 60 to 70 years for type B,[12] and hypertension contributes to 70 to 80 percent of cases.[30]

Despite marked treatment advancements since Shekelton's first efforts in the early 1800s, acute aortic dissection remains a lethal affliction. In the International Registry of Acute Aortic Dissection (IRAD) study from 2000, overall mortality stood at 27.4 percent, ranging from 26 percent for patients undergoing graft placement for ascending dissections to 58 percent for those managed medically. Mortality for patients with descending dissections stood at 10.7 percent for medical treatment compared with 31.4 percent for surgery.[12] Similarly, Meszaros et al.[31] found that 21 percent of patients succumbed before hospital admission. Each hour left untreated increases the risk of death: 22.7 percent within 6 h, 50 percent within 24 h, and 68 percent within the first week. When the dissection involves the ascending aorta, mortality follows rupture into the pericardium, dissection of the coronary ostia, and acute aortic regurgitation. In dissection of the descending aorta, mortality may result from visceral or extremity vessel obstruction or from aortic rupture.

Like DTAAs, aortic dissections may result from a myriad of pathologic processes. For instance, bicuspid aortic valves and the resultant aortic root dilatation are a well-established risk factor that is found in 7 to 14 percent of all aortic dissections.[12,30] Other aortic diseases ranging from the genetic to the congenital contribute to dissection: Marfan syndrome, Ehlers–Danlos syndrome, Turner syndrome, Noonan syndrome, coarctation of the aorta, annuloaortic ectasia, aortic arch hypoplasia, and aortic arteritis.[32] Common to many of those diseases is degeneration of the medial collagen and elastin, leading to diminished structural integrity of the aortic layers.

Beyond these diseases, medial degeneration seems to arise in dissection patients as a consequence of aging or hypertension; repetitive or excessive $dP/dt$ (change in pressure over change in time) slowly contributes to the breakdown of medial collagen and elastin.[33]

The acute versus chronic differentiation occurs at diagnosis 2 weeks after the initial onset of symptoms. Anatomically, two classification schemes prevail: the one proposed by DeBakey and colleagues in 1965 and the Stanford classification, although the former has more widespread use[34]:

- Type I: Dissection originates in the ascending aorta and extends through the aortic arch and into the descending aorta and/or abdominal aorta for a varying distance.
- Type II: Dissection originates in and is confined to the ascending aorta.
- Type III: Dissection originates in the descending aorta and is limited to that structure in type IIIa; type IIIb involves descending and variable extents of the abdominal aorta.

Daily and colleagues developed the Stanford classification scheme in 1970.[35] That system divides dissections into those originating in the ascending aorta (Stanford type A; DeBakey types I and II) and those confined to the descending aorta (Stanford type B; DeBakey types IIIa and IIIb). Here the discussion is limited to Stanford type B.

Over 93 percent of patients with acute aortic dissections present with pain, with 85 percent experiencing an abrupt onset.[12] Because dissection may occur anywhere along the course of the aorta, the precise location of the

pain varies: anterior chest pain radiating to the arm or jaw for type A dissections compared with back or intrascapular region for type B processes.[12,30] Complaints of abdominal pain in this setting raise the specter of mesenteric vascular compromise. True to traditional teachings, patients characterize the pain as "the worst ever" in 90 percent of cases, with a sharp (68 percent), ripping or tearing (50 percent), or migratory character (19 percent).[12] Although syncope presents in less than 3 percent of patients with acute dissection, it is a harbinger of a complex and often fatal course.[12] Patients who present with syncope are more likely to have a type A than a type B dissection (19 vs 3 percent, $p < 0.001$), more often have cardiac tamponade (28 vs 8 percent, $p < 0.001$), may have suffered a stroke (18 vs 4 percent, $p < 0.001$), and are more likely to die in the hospital (34 vs 23 percent, $p = 0.01$).[36] Spinal cord ischemia occurs in 2 to 10 percent of type B dissections as a consequence of the interruption of intercostal vessels.[37] Less commonly, patients may experience neuropathies from direct compression of a peripheral nerve: paresthesias from lumbar plexopathy, hoarseness from compression of the recurrent laryngeal nerve, and Horner syndrome secondary to sympathetic ganglion compression.

The natural history of aortic dissection predicts progression to aneurysmal dilatation. In fact, 20 percent of TAAs are attributable to chronic dissection in most series.[1] Factors that contribute to this evolution to aneurysm include poorly controlled hypertension, a maximal aortic diameter equal to or greater than 4 cm in the acute phase, and continued patency of the false lumen.[38] Ten to twenty percent of those with dissection subsequently have late rupture of the aneurysm.[39] Moreover, aneurysms that result from chronic dissection tend to be more extensive and occur in younger patients compared with degenerative aneurysms. Open surgical repair of type B dissections rarely is indicated emergently, except in the setting of threatened or actual rupture at the aortic intimal tear. In light of the substantial morbidity and complications associated with extensive aortic replacement in the emergent setting, some have argued for the abandonment of central aortic repair in the setting of type B dissection. The surgical results of open central aortic repair for dissection have not been overwhelming as 25 to 50 percent of these patients persistently have false lumen flow,[40] and surgeons have variable success in relieving distal malperfusion. More important, perioperative mortality ranges from 6 to 67 percent.[41]

Endovascular repair may emerge as a definitive and superior method to treat aortic dissection. An intuitive advantage of endovascular treatment is its ability to obliterate the false lumen by sealing the aortic tear with an aortic endograft. Continued patency of the false lumen has been noted to lead to aneurysmal dilatation.[38] Certain technical aspects of stent-graft placement merit emphasis. First, it is ill advised to place uncovered stents over the site of the entry tear within the proximal true lumen. It is not known whether an acutely dissected intimal flap can tolerate aggressive oversizing of the proximal aorta with a stent. Furthermore, the radial force of a stent may overdistend the true lumen in tortuous portions of the aorta. By these two mechanisms, deployment of such uncovered stents may cause aortic rupture, as has been confirmed in animal studies.[42]

A summary of select trials using stent grafts for aortic dissection is provided in Table 42-3.[41,43–47] Dake et al. reported outcomes of stent-graft therapy for type B dissections after their initial experience with homemade devices in 15 patients.[43] Two patients required deployment of a second stent because of residual flow in the false lumen from proximal or distal communication. In that initial series, three patients died (20 percent): two from false lumen rupture hours to days after stent grafting and the third from sepsis 7 days later, apparently as a result of malperfusion syndrome. Their complication rate stood at 20 percent, including gut infarction, leg gangrene, pneumonia, and renal failure. However, stent grafting was successful in achieving complete thrombosis of the false lumen in 12 of the 15 surviving patients. These authors advocated stent grafts

to protect against end-organ ischemia but also emphasized the importance of promptly sealing an intimal tear to preclude progression to aneurysm.

Nienaber et al. published their early endovascular experience concurrently with the study mentioned above.[44] Their trial compared 12 consecutive patients with type B dissections treated with stent grafts to matched controls who were treated operatively. Whereas Dake and co-investigators had used custom-designed stents, Nienaber used commercially available components with uncovered proximal fixation. Although surgical treatment accrued 33 percent morbidity ($p = 0.09$) and 42 percent mortality ($p = 0.04$), those with stent grafts experienced no morbidity or mortality within 12 months. Ten of the twelve patients experienced immediate thrombosis of the false lumen after graft deployment, with the remaining patients demonstrating thrombosis at 3-month follow-up. Compared with surgical therapy, those undergoing endovascular treatment had a shorter stay in the ICU ($p < 0.001$), a shorter hospital course ($p < 0.001$), and lower overall mortality ($p = 0.04$). That group concluded that not only may stent-graft treatment of thoracic aortic dissections offer substantial cost savings, it is also associated with lower morbidity and mortality than open repair.

More recently, Xu and colleagues[45] reported their experience from 2001 to 2005 of 63 consecutive patients with type B thoracic aortic dissection treated with TEVAR. In this series, the perioperative mortality was 3.2 percent with a 4-year actuarial survival of 89.4 percent. In this group, TEVAR was complicated by the induction of ascending dissection during two procedures. One year post procedure, CTA showed a decrease in the size of the false lumen (average diameter decrease of 11.2 percent) and an increase in the true lumen in most patients. In addition, complete thrombosis of the false lumen was achieved in over 98 percent of patients. The authors concluded that early and midterm results demonstrate that TEVAR is an effective means of treating acute type B dissection of the thoracic aorta.

A common indication for open operation on a type B dissection remains the potential for life-threatening complications including renal and visceral malperfusion and rupture or imminent rupture. Although open replacement has frequently been undertaken for these indications, the role of endovascular treatment is less well characterized. Szeto and colleagues[46] therefore reported their institutional experience with emergency TEVAR in 2008. From 2004 to 2007, 35 patients with acute complicated type B aortic dissection were treated with TEVAR. In their series, 51 percent of patients had rupture and 49 percent had malperfusion of the mesentery, kidneys, and/or lower extremities. Overall, they reported only one perioperative mortality secondary to failure to cover the primary tear site resulting in free rupture on postoperative day 3. At 13-month follow-up, there was one additional death, and three patients required aortic reintervention, one for dissection of the ascending aorta, one for persistent endoleak, and one for a sinus of Valsalva aneurysm. In acute life-threatening type B aortic dissection, TEVAR is a safe and effective means of treatment; however, sufficient coverage of the primary dissection site is crucial to prevent complications.

Although most series evaluating endovascular treatment of aortic dissection are small, a recent meta-analysis of the literature was undertaken by Parker and colleagues[47] to further characterize this patient population. This analysis examined 942 patients who presented with acute type B aortic dissection and were treated with TEVAR. Perioperative mortality was 9 percent, and 20-month survival was 88 percent. Late aortic rupture occurred in 0.8 percent of patients while 7.6 percent of patients required endovascular reintervention and 2.8 percent of patients required open surgical reintervention. The early, favorable outcomes in this study of many different centers suggest that TEVAR can be broadly applied to patients with aortic dissection with acceptable outcomes.

### Johns Hopkins Approach the Management of Aortic Dissection

At the Johns Hopkins Hospital, we approach the management of aortic dissection as outlined in Figure 42-6. In general, endovascular repair is reserved for patients with an acute presentation and evidence of malperfusion.

## HYBRID APPROACH TO THORACOABDOMINAL AORTIC ANEURYSMS

TAAs continue to represent one of the most challenging pathologies encountered by vascular surgeons. This condition is highly lethal when managed medically but accompanied by significant morbidity and mortality when managed surgically. Although significant progress has been made with traditional surgical management, with large institutional series demonstrating mortality rates less than 10 percent, national series continue to demonstrate a mortality rate closer to 20 percent with a 15 percent rate of permanent paraplegia and 20 to 30 percent incidence of renal failure.[48,49]

Given the high morbidity and mortality associated with the traditional, open repair of TAAs, surgeons have investigated various endovascular approaches to this problem. The most common technique to circumvent an open TAA repair is the utilization of a hybrid procedure combining open visceral and renal debranching with endovascular aortic stenting. Theoretically, hybrid procedures avoid the need for aortic cross-clamping, single lung ventilation, and partial LHB.[48]

Early results of hybrid TAA procedures were promising. Black et al.[49] reported their 29-patient series in 2006. They found a perioperative mortality of 13 percent and no paraplegia. However, the results of subsequent studies have been more complex. In these series, perioperative mortality ranges from 14 to 24 percent[50–52] with a morbidity of 25 to 31 percent[51,52] and a paraplegia rate of 0 to 11 percent.[50,52] Moreover, Chiesa and colleagues[51] found that hybrid procedures had similar morbidity and mortality as traditional

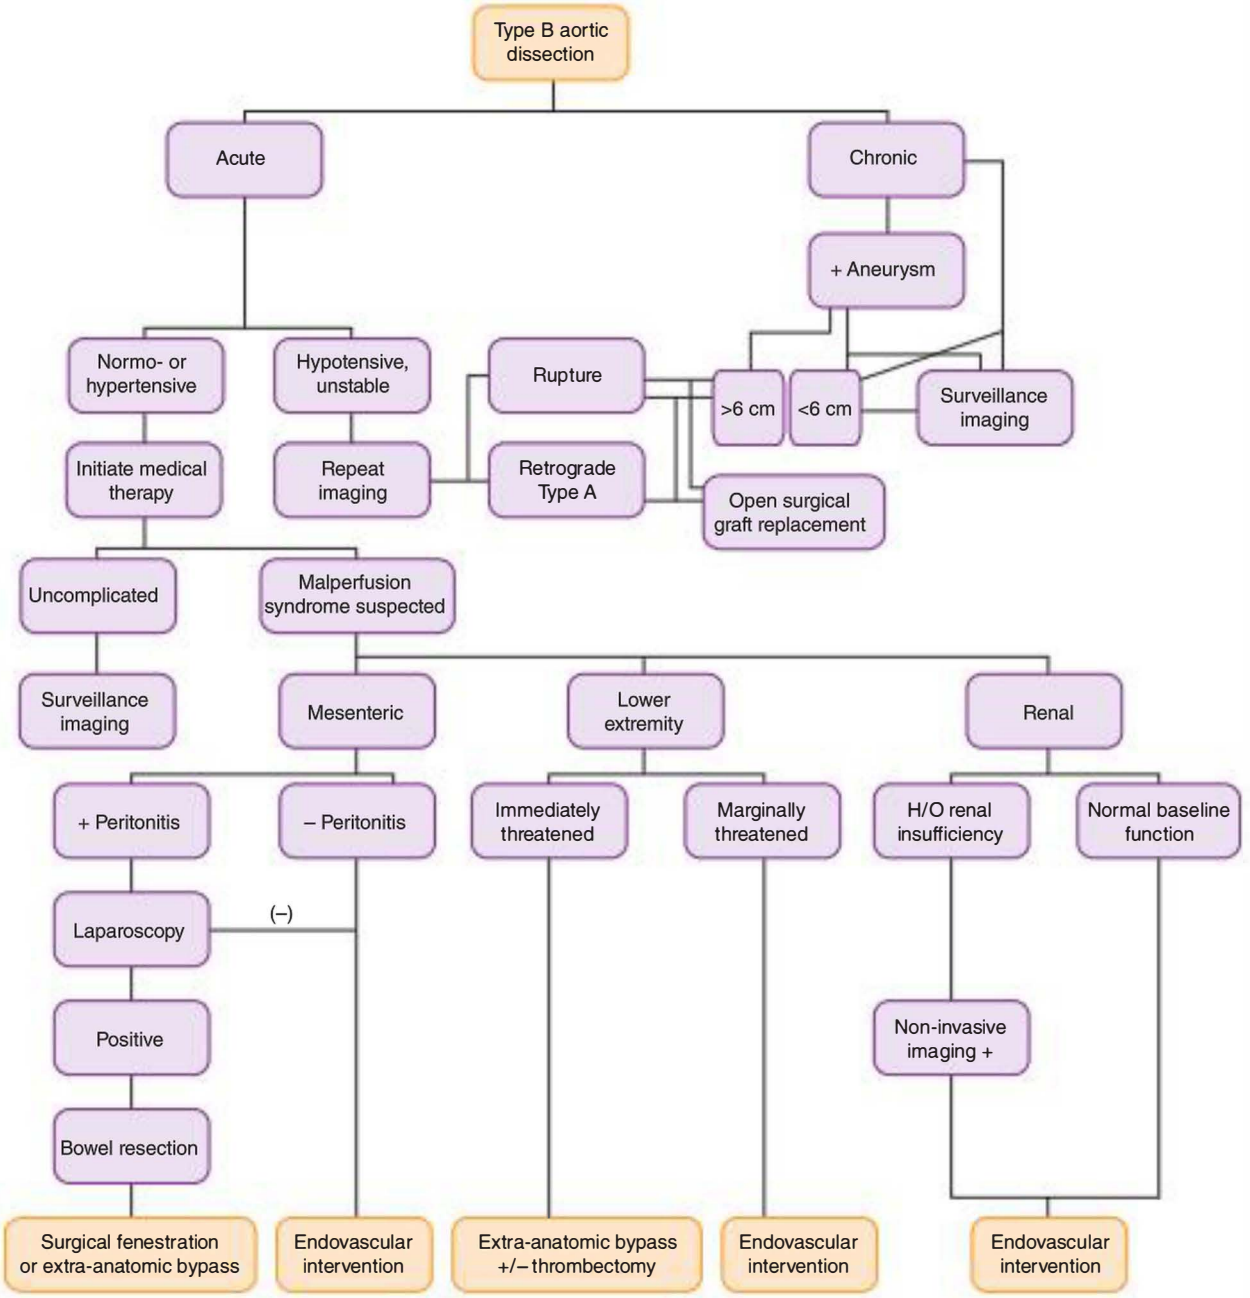

**FIGURE 42-6** The Johns Hopkins Hospital approach to aortic dissection.

open procedures, though their numbers were small. Of note, in most series, hybrid approaches were undertaken because the patients were thought to be too high risk for traditional TAA repair.

In summary, early results with hybrid approaches to TAAs are promising, and although subsequent studies have failed to demonstrate significant advantages, contemporary studies are small and underpowered to detect a difference. This problem is further complicated by the wide range of aneurysmal extent reported in these studies (Crawford I–IV) and wide variability in comorbidities and prior aortic surgery. Moreover, many questions including the timing of the staged operations (simultaneous vs delayed) remain to be elucidated. Large, multicenter, prospective data are needed to determine which patient population is most likely to benefit from this alternative therapy.

## PENETRATING ATHEROSCLEROTIC ULCERS AND INTRAMURAL HEMATOMAS

First described by Shennan in 1934, penetrating atherosclerotic ulcers (PAUs) were characterized fully by Stanson and colleagues in 1986.[53] IMHs were described earlier by Krukenberg in 1920.[54] Diagnostically, IMHs are confirmed by regional aortic wall thickening over 7 mm on CT scan or MRI in the absence of an intimal flap and without enhancement after contrast injection (Fig. 42-7).[55] Each of these entities presents much like aortic dissection, with sharp chest (ascending aorta) or back (descending aorta) pain.[56] In fact, among patients with acute aortic symptoms, 5 to 15 percent of cases are attributable to IMH.[57]

Cases of IMH with PAU tend to occur in the descending thoracic aorta (type B), whereas cases of IMH without PAU are grouped in the ascending aorta (type A). Ascending PAUs carry a 57 percent mortality while descending PAUs result in 5 percent mortality and 12 percent dissection.[57] Similarly, 28 percent of cases of type A IMH ended in aortic rupture, compared with only 9 percent of cases of type B IMH in the study by von Kodolitsch et al.[58] Moreover, 25 percent of cases of IMH without PAU progressed to dissection in the ascending aorta, whereas 13 percent did in the descending aorta. Thus, it has been suggested that type B IMH may be treated conservatively, whereas type A IMH warrants aggressive management.[55]

From the pathologic perspective, PAUs and IMHs seem to exist on a continuum: When a PAU gains intramural access of sufficient depth, the dissecting process commences, leaving a crescentic ring of blood in the aortic wall characteristic of IMHs. IMHs originate in severely diseased aortas that have been subject to severe hypertension. Unlike dissection, no intimal tear is visualized radiographically with IMHs. Nonetheless, a crescentic column of clotted blood fills the space that would be the false lumen in a typical dissection.[56]

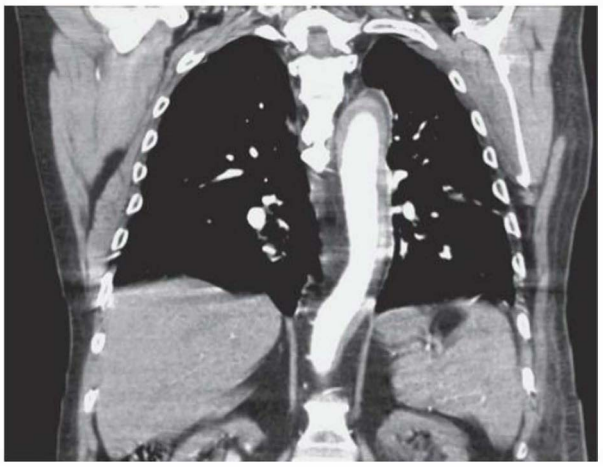

**FIGURE 42-7** Computed tomography, coronal view, of an intramural hematoma.

Explanations for the origin of this blood have ranged from the spontaneous rupture of the vasa vasorum, to the fracture of an atheromatous plaque, to disruption of a PAU that violates the internal elastic lamina, allowing transit of blood into the layers of the aortic wall.[59,60]

The natural history of IMHs has been reported to range from progression, to false aneurysm, to spontaneous regression, to dissection, and even to rupture.[55,56] A recent report correlated initial aortic diameter with progression to a catastrophic result from IMH; patients presenting with an initial aortic diameter greater than 40 mm had a 30-fold increased risk of progression to aneurysm formation or rupture. Furthermore, progression was nine fold more common in patients with an initial aortic wall thickness greater than 1 cm.[61] However, PAUs carry a more severe prognosis than do IMHs: Forty to fifty percent of acutely symptomatic patients progress to acute dissection or aortic rupture during the initial hospital admission.[62] Uncontrollable pain, increasing pleural effusion, and larger diameter and depth of PAU all portend progressive disease courses.[57] Therefore, early surgical intervention is recommended for symptomatic penetrating ulcers.[63]

Patients with PAU tend to be older and to have multiple comorbidities. Coady et al.[59] found a mean age of 77 years compared with 54 years for type A and 67 years for type B dissections ($p = 0.01$).[59] Associated comorbidities include hypertension,[53,55] COPD, and CAD.[21,57] Fully 40 percent of patients with PAU have been treated previously for AAA, a figure that indicates their extensive degenerative disease. Moreover, these patients carry a more severe prognosis than do those with dissection with a mortality rate of 40 vs 7.3 percent for type A and 4 percent for type B dissection.

Several studies have examined the outcomes of PAUs treated with TEVAR (Table 42-4).[64–66] Patel et al.[66] reported their experience with 37 patients in 2010. In this series, indications for intervention included rupture, symptoms, or the formation of a saccular aneurysm in an asymptomatic patient. Other patients were managed medically. Patients considered high risk for traditional open repair or who desired endovascular repair and had favorable anatomy

**TABLE 42-4: Results of Endovascular Repair of Penetrating Atherosclerotic Ulcers**

NR, not reported.

were treated with TEVAR. All procedures were technically successful. In-hospital mortality was 5.4 percent, with both patients succumbing to ruptured aneurysms. No patients suffered permanent paraplegia. Actuarial freedom from TEVAR treatment failure was 81.6 percent at 5 years. On multivariate analysis, patients with IMH associated with their PAU were at higher risk of treatment failure. Thus, in this elderly and often debilitated patient population, TEVAR is a safe and effective treatment. Since patients with an associated IMH are at higher risk of treatment failure, careful assessment of the need for immediate versus delayed therapy is warranted.

## ENDOVASCULAR MANAGEMENT OF THORACIC AORTIC TRAUMA

Blunt aortic injury (BAI) secondary to trauma is a devastating injury. Over 85 percent of these patients die on the scene[67] and most who survive to the hospital suffer from multisystem injuries, rendering open surgical repair an unattractive option. Open surgical repair carries a mortality rate of 18 to 31 percent with a paraplegia rate of 2 to 14 percent[67,68]; however, without surgery, mortality can be as high as 55 percent.[67] Given the substantial morbidity and mortality associated with open repair of BAI, there is an increasing trend toward endovascular treatment of traumatic aortic injury. In fact, as of 2008, approximately 65 percent of BAI are treated endovascularly.[69]

The diagnosis of BAI was traditionally made with chest x-ray (CXR). Plain film criteria for aortic injury include loss of the aortopulmonary window, an abnormal aortic arch, a rightward tracheal shift, and a widened mediastinum.[67] However, 20 percent of patients with BAI have a normal CXR.[70] The long time gold standard for diagnosis was aortography (Fig. 42-8); however, in a landmark study, Fabian et al. demonstrated that helical CT scanning had a greater sensitivity for detecting BAI than did aortography (100 vs 92 percent).[70] Thus contemporary recommendations suggest helical CT for unrestrained patients involved in accidents at speeds greater than 10 mph and restrained patients in accidents greater than 30 mph.[67]

**FIGURE 42-8** Computed tomography, sagittal view, of a traumatic aortic transaction at the isthmus opposed to the left subclavian artery (LSA). LSA coverage anticipated. Narrow arches in young trauma patients present challenges to current devices.

Although immediate repair of BAI is recommended, it is often not possible secondary to multisystem injuries. Several studies have shown that delayed repair is safe if medical treatment with β-blockade and antihypertensive is undertaken. Fabian et al.[70] have demonstrated that while nonoperative management carries a high mortality rate, none of the patients in their series who were managed medically died from ruptured BAI. Other studies corroborate this finding, with an aortic-related mortality in patients managed medically of 4.8 percent.[71] In addition, in a large retrospective study, Estrera et al.[72] reported only 1 death (2 percent) from delayed repair. In fact, on multivariate analysis, delayed repair was protective against early mortality.

The results of endovascular treatment for traumatic aortic pathology are summarized in Table 42-5. The 2002 study by

PSA, pseudoaneurysm; NR, not reported.

Bortone et al.[41] included a subset of patients with traumatic aortic pseudoaneurysms. Those authors achieved 100 percent technical success with no deaths or paraplegia. There was 1 patient among 10 who required removal of his stent at 2 weeks secondary to compression of the left mainstem bronchus. As with thoracic aortic dissections, those authors advocated immediate endovascular repair rather than waiting more than 2 weeks: Delayed treatment is thought to be associated with the creation of fibrous and calcified connective tissue in the aortic wall, leading to further complications in treatment. In contrast, in the 6 patients (of 10) treated within 2 weeks of traumatic aortic pseudoaneurysm, aortic wall healing was seen in the 1-year follow-up CT scan.[41]

Neschis et al.[69] treated 43 consecutive patients from 2004 to 2008 with traumatic aortic injury with TEVAR. In their series, 13 patients needed exploratory laparotomy, 3 needed fracture fixation, and 1 needed a craniotomy resulting in an average aortic repair delay of 7 days. They reported a perioperative mortality of 11.6 percent, none related to endograft complications, and no permanent paraplegia. However, 14.3 percent of repairs were complicated by endoleaks and three of these patients eventually had open repair with endograft explantation. This study suggests that in patients with anatomically suitable lesions, endovascular intervention is the preferred treatment of BAI. This conclusion is supported by other studies demonstrating that TEVAR carries a lower rate of mortality than all types of open repair, included procedures involving clamp-and-sew, distal aortic perfusion, and cardiopulmonary bypass.[72]

Although a consensus is emerging that endovascular repair of BAI is the treatment of choice in anatomically acceptable candidates, with improved morbidity and mortality, the long-term durability of these devices remains unknown. This is a particularly important consideration as trauma patients with BAI tend to be much younger than the aneurysmal patients more commonly treated with these devices.

## COMPLICATIONS

The emergence of thoracic aortic stent grafting as the primary and often preferred treatment modality for many aortic pathologies has introduced a new spectrum of complications. Three areas merit special attention: spinal cord ischemic injury (SCI), retrograde dissection into the arch, and the consequences of left subclavian coverage.

SCI manifesting as paraplegia or paraparesis has been reported in several series, with an incidence of 0 to 12 percent.[73] The mechanism of the occurrence of SCI is not completely understood but may involve both primary spinal artery interruption by coverage by stent grafting and hypoperfusion caused by hypotension, which renders the collateral supply ineffective in spinal cord homeostasis. Evidence for this hypothesis stems from the open surgical literature and the elevated risk appreciated in patients undergoing thoracic endografting in whom prior AAA repair was performed (because lumbar arteries were oversewn).

A recent report by Cheisa et al.[74] examined perioperative risk factors to attempt to predict which patients would be at the highest risk for SCI. Over 5 years, 103 patients underwent endovascular repair of thoracic aortic disease ($N = 88$ TAA, $N = 10$ type B dissection, $N = 5$ PAU). CSF drainage was employed in seven patients on the basis of prior AAA repair or the need to cover T8 to L2 critical intercostals/lumbars. SCI was noted in four patients (4 percent), with all deficits occurring 24 to 96 h after the primary procedure. All deficits resolved with the institution of CSF drainage, steroids, and maintenance of MAP above 90 mm Hg. All patients with SCI were noted to have the lowest perioperative MAP below 70 mm Hg ($p < 0.001$). No other preoperative demographic or anatomic correlate of the procedure was significant on univariate analysis. In addition, other series have reported that the length of aorta covered with endografts is independently associated with the risk of spinal cord ischemia.[75] Accordingly, vigilance should be maintained in the perioperative period to avoid arrhythmias, anemia, and hypotension, particularly with intervention on a significant distance of the aorta, as spinal perfusion pressure may be marginal in the immediate perioperative period.[74]

Retrograde dissection (into the arch and ascending aorta) created by the mechanical force of the thoracic stent-graft interfacing with the proximal aorta has been described.[76] It is important to recognize that this may occur during, immediately after, or weeks after the primary thoracic stent-graft implantation. In a report by Eggebrecht and coworders,[77] there were 63 reported cases of retrograde ascending aortic dissection reported from the 28 centers participating in the European Registry on Endovascular Aortic Repair Complications, an incidence of 1.33 percent. Of these, 81 percent occurred in patients undergoing TEVAR for dissection. In this series, 42 percent were fatal. Most (64 percent) were discovered during follow-up, with 25 percent being asymptomatic and 19 percent presenting with sudden death. Although the association with dissection suggests that some cases of retrograde dissection result from a progression of the underlying disease, many likely result from procedure-related damage to the aortic wall either from the graft itself or from manipulation of guide wires and sheaths. Violation of the aortic wall creates the nidus that subsequently blossoms into a florid dissection. The variability in presentation, timing, and location underscores the need for regular surveillance of all patients who have been treated with the emerging technology of thoracic aortic endografting.

Coverage of the LSA for the purpose of extending the length of a proximal aortic seal has undergone a significant change in its treatment paradigm. Theoretical concerns about left upper extremity ischemia are not commonly encountered clinically. However, collateral supply to the spinal cord may derive from the thyrocervical trunk, which is dependent on LSA perfusion. Therefore, coverage of the LSA can be associated with rare but devastating neurological sequelae. Although a recent series of 171 patients demonstrated an absence of true malperfusion syndrome,[78] several centers are routinely revascularizing covered LSAs

prophylactically[79] In a landmark trial of over 600 TEVAR patients, there was an 8.4 percent incidence of paraplegia or stroke in patients who had LSA coverage versus a 0 percent incidence in those who underwent prophylactic revascularization.[80] These potential neurological sequelae have led some to rethink their approach to LSA coverage. Many have suggested definition of the head and neck arterial anatomy with CTA, recommending consideration of elective revascularization for the following indications: small right subclavian artery; patent left internal mammary coronary artery bypass; patent left axillary–femoral bypass; functional left arm arteriovenous fistula; patient left-handedness; aberrant aortic arch anatomy; or extensive thoracic aortic coverage with a history of prior abdominal aortic procedures.[81,82]

## SUMMARY

Stent-graft therapy of the full spectrum of thoracic aortic pathologies is a rapidly developing and emerging technology. On the basis of satisfactory early and midterm results combined with the obvious avoidance of major cavitary incisions and recovery thereafter, thoracic aortic stent grafting has assumed a role as a primary therapy for aneurysms, dissections, penetrating aortic ulcers, and traumatic lesions. Not only have endovascular surgeons recognized the advantages of thoracic stent grafts, patients are demanding consideration for such "minimally invasive" options. Open thoracic aortic surgery may become reserved for cases in which anatomy and topography prohibit safe graft implantation. Surgeons who want to apply this technology to benefit their patients must conduct appropriate preoperative planning and imaging, have a solid base of fundamental skill with catheter-based interventions, and recognize the need for regular, lifelong surveillance of all patients treated with thoracic aortic endografts.

## ENDOVASCULAR REPAIR OF THORACIC AORTIC PATHOLOGY BOARD REVIEW QUESTIONS (CHAPTER 42)

1. Which of the following is the optimal study for evaluation of blunt aortic injury?
   A. Plain radiography
   B. Aortography
   C. Computed tomography
   D. Transthoracic echocardiography
   E. Serum biomarkers

2. Which of the following is correct regarding endoleak?
   A. Type I = poor seal between the graft and the proximal aorta
   B. Type II = poor seal between the graft and the distal aorta
   C. Type III = blood leakage through the graft material
   D. Type IV = back bleeding from branch vessels
   E. Endoleak occurs in less than 10 percent of patients.

3. Which of the following is not associated with increased risk of spinal cord ischemia during endovascular thoracic interventions?
   A. Prior aortic surgery
   B. Hemodynamic instability
   C. Length of aortic coverage
   D. Cerebrospinal fluid drainage
   E. Left subclavian coverage

4. Which of the following is true regarding endovascular repair of descending thoracic aortic aneurysm?
   A. The cost is equivalent to open repair.
   B. Mortality is higher than open repair.
   C. There has not been evaluation for the treatment of ruptured aneurysm.
   D. Only one device is FDA-approved for treatment of aortic aneurysm.
   E. Technical success is variable.

5. Which of the following is not a potential indication for prophylactic left subclavian artery revascularization prior to left subclavian artery coverage with a thoracic endograft?
   A. Patent left internal mammary artery to left anterior descending artery graft
   B. Absent or atretic right vertebral artery
   C. Patent left arm arteriovenous dialysis shunt
   D. Heavily calcified or stenotic left subclavian artery origin
   E. History of prior abdominal aortic procedures

## ANSWERS

1. **Answer: C.** Computed tomography (CT) is the best study to evaluate blunt aortic injury, as it is highly sensitive, noninvasive, and rapid. Plain chest radiographs will be normal in 20 percent of patients with blunt aortic injury. Aortography is less sensitive and more invasive than CT. TTE is less sensitive and specific than CT and is unable to image the aortic arch.

2. **Answer: A.** A type I endoleak occurs when there is inadequate seal between the graft and the distal or proximal aorta. A type II endoleak occurs when there is back bleeding from branch vessels. A type III endoleak occurs when there is blood excursion between graft components. A type IV endoleak occurs when there is blood leakage through the graft material. Endoleak is common, occurring in 13 to 30 percent of patients.

3. **Answer: D.** In several randomized trials, cerebrospinal fluid has been associated with a decreased risk of spinal cord ischemia. Prior infrarenal abdominal aortic aneurysm repair, hemodynamic instability, increasing length of endograft aortic coverage, and left subclavian coverage have all been associated with increased risk of spinal cord ischemia.

4. **Answer: A.** Endovascular repair of descending thoracic aortic aneurysm has a similar cost to open repair, as the high cost of the devices offset the shorter hospitalization. TEVAR has a similar mortality to open repair and has been shown to effective and safe for the treatment of ruptured aneurysms. There are currently three FDA-approved devices, all of which have high technical success rates.

5. **Answer: D.** A heavily calcified or stenotic left subclavian artery origin will likely not require prophylactic left subclavian artery revascularization. The remaining conditions can potentially result in compromised flow to the heart (left internal mammary artery graft), the brain (absent/atretic right vertebral artery), access (left arm dialysis shunt), or the spinal cord (prior abdominal aortic procedures) after occlusion of the left subclavian artery with an endograft.

# Surgical Therapies for Atrial Fibrillation

*Timo Weimar*
*Ralph J. Damiano Jr.*

**KEY CONCEPTS**

- Epidemiology
  - Atrial fibrillation (AF) affects about 2 percent of the general population. It is strongly correlated to age and the prevalence increases to 10 to 15 percent in patients over the age of 80. It is associated with hypertension, heart failure, valvular heart disease, and ischemic heart disease. In 10 to 15 percent there is no underlying cardiac pathology present (lone AF).
- Pathophysiology
  - AF requires both an initiating event and a permissive atrial substrate. While automaticity and triggered activation is often, but not exclusively, found within and around the pulmonary veins and is involved in AF initiation, different mechanisms of reentry in both atria also play an important role in sustaining AF. As the atrial size increases, the conduction velocity slows or the atrial refractory period decreases, and the probability of initiating and sustaining AF increases.
- Clinical features
  - Besides symptoms, hemodynamic compromise, and tachycardia-induced cardiomyopathy, stroke remains the most feared complication. AF accounts for about 25 percent of strokes in patients older than 80 years and increases a person's risk of stroke by 5-fold.
- Diagnostics
  - A transthoracic and transesophageal echocardiogram should determine left atrial diameter and evaluate for the presence of a left atrial thrombus. A cardiac catheterization will provide information about the presence of coronary artery disease and the anatomical location of the circumflex coronary artery. In patients who have failed catheter ablation, chest computerized tomography (CT) is indicated to assess for pulmonary vein stenosis.
- Treatment
  - The surgical procedures currently performed to ablate AF include the biatrial Cox-Maze procedure (CMP), left atrial lesion sets, and pulmonary vein isolation. All of these operations have been simplified by alternative energy sources.
- Outcome
  - Success rates vary and depend on the lesion set performed, the energy source used, the type of AF, and the presence of concomitant pathology. The biatrial CMP has an approximately 90 percent success rate for all types of AF and has set the benchmark for alternative lesion sets as well as for new and less invasive approaches currently under development.

## INTRODUCTION

Atrial fibrillation (AF) is the most common sustained arrhythmia worldwide with an increasing incidence with age. Adults at the age of 40 years have a 25 percent risk of developing AF during their lives.[1] The actual incidence and prevalence of AF is likely underestimated due to undetected asymptomatic occurrences or patients ignoring paroxysmal episodes. Experts predict that the number of AF-related hospitalizations will increase and almost double to 3.5 million by the year 2025 in the United States.

Although AF itself is not considered a life-threatening arrhythmia, it is associated with significant morbidity and mortality secondary to hemodynamic compromise and tachycardia-induced cardiomyopathy in some patients. Besides palpitations resulting in discomfort and anxiety, the loss of synchronous atrioventricular contractility may cause various degrees of ventricular dysfunction, exercise

intolerance or congestive heart failure in patients with AF. Furthermore, stasis of blood flow in the fibrillating left atrium increases the risk of thrombus formation. Thromboembolic events and stroke remain the most feared complication in these patients. AF accounts for about 25 percent of strokes in patients older than 80 years and increases a person's risk of stroke by 5-fold.[2] Overall, AF has been identified as an independent risk factor for mortality. Using the data from the Framingham study, the established risk factor–adjusted odds-ratio for death in men and women with AF was 1.5 and 1.9, respectively.[3]

The pharmacological treatment of AF has been disappointing with failure rates as high as 60 percent. Besides the significant side effects associated with antiarrhythmic drugs, their long-term efficacy in maintaining normal sinus rhythm is poor. In the AFFIRM-trial, rhythm control strategies were compared to rate control and anticoagulation. There was no survival benefit of rhythm over rate control. This appeared to be due to the use of antiarrhythmic drugs to maintain sinus rhythm as the AFFIRM-trial confirmed that the presence of normal sinus rhythm significantly decreased the risk of death with a hazard ratio of 0.53 ($p$ <0.001).[4]

The persistent limitations of pharmacological therapy of AF have led to the development and proliferation of interventional approaches in the treatment of AF over the past two decades. The most promising and successful options have included catheter ablation and surgery. Strategies for interventional treatment have been based on the type of AF. A recent consensus statement of the Heart Rhythm Society, the European Heart Rhythm Association, the American College of Cardiology, the American Heart Association, and the Society of Thoracic Surgery defined three different types of AF including paroxysmal, persistent, and longstanding persistent AF (Table 43-1).[5] The foundation of catheter ablation has been the isolation of the pulmonary veins (PVI). Results have been variable with single-procedure success rates between 16 and 84 percent.[5] Although PVI has had good success rates in most patients with paroxysmal AF, certain patient subgroups have done poorly, such as patients with longstanding persistent AF and large atria. A recent report from Haïssaguerre's group, who pioneered PVI, reported a single procedure success rate as low as 29 percent after 5 years.[6] The surgical treatment of AF has had higher success rates in preventing AF recurrence. The biatrial Cox-Maze procedure (CMP) III has been the gold standard for more than one decade, with a freedom from symptomatic AF of 97 percent, and has been equally effective in all types of AF.

**TABLE 43-1: Definition of Atrial Fibrillation**

*Paroxysmal AF* is defined as recurrent AF (≥2 episodes) that terminates spontaneously within 7 days

*Persistent AF* is defined as AF that is sustained beyond 7 days or lasting less than 7 days but necessitates pharmacological or electrical cardioversion

*Longstanding persistent AF* is defined as continuous AF of greater than 1-year duration

The term *permanent AF* refers to a patient group where a decision has been made not to pursue restoration of sinus rhythm by any means, including catheter or surgical ablation

## PATHOPHYSIOLOGY OF ATRIAL FIBRILLATION

AF is a manifestation of a complex and progressive disease of the atria with electrical, contractile and structural remodeling that, in most incidences, gradually worsens over time.[7]

There are four main components that play an important role in the initiation and sustention of AF: (1) a trigger, which can be a single premature or a run of focal ectopic depolarization; (2) the effective atrial refractory period; (3) the conduction velocity; and (4) the geometry or anatomy of the atrium. Although the precise mechanisms that cause AF are incompletely understood, AF appears to require both an initiating event and a permissive atrial substrate. There is supportive data for multiple wavelets, mother waves, fixed or moving rotors, and macro-reentrant circuits playing a role in AF, and in a given patient, multiple mechanisms may coexist at any given time.

### Automaticity and Triggered Activity

Enhanced automaticity occurs when myocytes possessing pacemaker activity increase their rate of spontaneous discharge. It can be due to a lowered threshold of the action potential upstroke, a less negative maximal diastolic potential, or an increase in the slope of spontaneous diastolic depolarization. Triggered activity arises from membrane oscillations following normal action potentials. If such oscillation reaches threshold of depolarizing currents, they can provoke new action potentials. Under certain circumstances, such triggered responses can in turn elicit new action potentials, resulting in self-sustaining runs of triggered activity. After Haïssaguerre and colleagues reported on the role of pulmonary veins (PVs) in initiating AF, most interventional treatment strategies focused on the isolation of triggers from these anatomic sources.[8] While paroxysmal AF often initiates in the PVs, biatrial mapping studies have shown that the premature beats that trigger AF were located in the PVs in only 53 percent of the time. However, data about the presence of pacemaker cells in the PVs or other atrial areas outside the sinus node are controversial. The conduction velocity within the PVs is slower (0.3 m/s) compared with the surrounding atrial tissue (0.9 m/s). The complex fiber orientation spiraling perpendicularly around the vein with other fibers running parallel to the vein, and the lack of Connexin 40 in the veins, a major determinant of conduction velocity in the atria, probably contribute to this slower conduction. This creates heterogeneity of electrical conduction around the PVs, which is theorized to promote reentry and sustained

AF. Although the PVs have the substrates needed to initiate and maintain AF in some patients, in almost 50 percent of cases there are sources present outside the PVs. In the group of patients undergoing concomitant cardiac surgery for structural heart disease, it is important to remember that the underlying mechanisms cannot be necessarily translated from experiences drawn from the electrophysiological laboratory with lone AF.

## Mechanisms of Reentry

There are multiple theories for the development of reentrant circuits in the atrium.[9] *Circus movement reentry* is characterized by an activation that can travel around a preformed anatomical structure, like the orifice of the PVs, and reactivate previously excited tissue. A short refractory period and a low conduction velocity make circus movement reentry more likely. The minimal path length for circus movement reentry can be calculated as the product of conduction velocity and refractory period (wavelength). If the path of the circuit is longer than the wavelength, there is a delay between recovery of the tissue and the moment of reexcitation, which is called the "excitable gap" (Fig. 43-1A). Initiation of *circus movement reentry* requires unidirectional conduction block often occurring in regions with long refractory periods.

In the *leading circle concept*, the reentrant circuit does not require an anatomical obstacle but rather moves around a core that is not fully activated. The dynamics of reentry are determined by the smallest possible loop in which the impulse can continue to circulate. Under this condition, the wavefront must propagate through relatively refractory tissue, making it a relatively unstable reentrant since there is no fully excitable gap (Fig. 43-1B). In the *spiral wave theory*, the rotor rotates around an unexcited yet excitable core. Along the wavefront, there is a decline in conduction velocity until block occurs (dotted line in Fig. 43-1C). One way of visualizing such a wave is to think of a broken wave that curls at its broken end and begins to rotate. Multiple unstable rotors resemble conduction patterns similar to that of the *multiple wavelet hypothesis*. According to Moe's computer simulation, wavefronts continuously undergo wavefront–wavetail interactions resulting in wave breaks and generation of new wavefronts (Fig. 43-1D).

As the underlying distribution of refractory periods becomes more heterogeneous, unidirectional block can occur. This is a necessary condition for the initiation of reentry. When unidirectional block occurs, reentrant arrhythmia will initiate only if a critical mass of tissue is present. The critical mass is determined by the wavelength of the reentrant circuit. As atrial size increases, conduction velocity is slowed or the atrial refractory period is decreased, and the probability of initiating and sustaining AF increases. Although numerous non-pharmacologic approaches to treat AF, like isolating triggers in PVs, have involved altering one of these substrates, it must be remembered that the other substrates can still be active.

## Atrial Remodeling

Studies of Alessie in the early 1990s advanced our understanding of AF by the observation that AF itself induces changes in the atrium that result in an increased susceptibility to further AF.[10] He demonstrated that, during atrial pacing, action potential duration and atrial refractory period both decreased. This electrical remodeling led to sustained AF. However, structural changes of the atrium contribute to this remodeling process as well. Age, hypertension, congestive heart failure, or heart valve diseases are all strong predictors for the development of AF. These characteristics all increase atrial wall stress and some degree of dilatation in the atria by increased volume or pressure load. All these conditions can be the cause of the development of fibrosis and myocyte hypertrophy. These pathological changes can result in slow conduction or conduction block in some areas of the atrium, further increasing susceptibility to AF.

# EPIDEMIOLOGY

AF affects about 2 percent of the general population and almost 3 million people in the United States. It is strongly correlated to age and the prevalence increases from 0.1 percent in persons younger than 55 years to about 5 percent in persons 60 years or older and approaches 10 to 15 percent for patients over the age of 80. Overall, significantly more men than women are affected by AF.

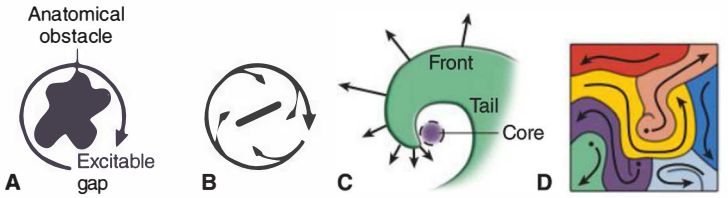

**FIGURE 43-1** Mechanism of reentry: **A.** Circus movement reentry. **B.** Leading circle concept. **C.** Rotor theory reentrant. **D.** Multiple wavelet hypothesis. (Reproduced with permission from Schotten U, et al. Pathophysiological mechanisms of atrial fibrillation: A translational appraisal. *Physiol Rev* 2011;91:265–325.)

There are a number of cardiovascular disorders associated with AF including hypertension, heart failure, valvular heart disease, and ischemic heart disease. All of these comorbidities can cause increased stress on the atrial wall resulting in interstitial fibrosis and atrial dilatation. However, in 10 to 15 percent of patients, there is no underlying cardiac pathology present (lone AF).

Stasis of atrial blood and resultant thrombus formation associated with AF increases a person's risk of stroke by 5-fold and the rate of stroke averages about 5 percent/year in affected patients. It increases substantially in the presence of other cardiovascular diseases. While the prevalence of stroke is low in patients under the age of 60 at less than 0.5 percent, it approaches 30 percent for patients between 80 and 90 years. The intensity of anticoagulation involves a balance between prevention of ischemic stroke and avoidance of hemorrhagic complications. An international normalized ratio (INR) of 2 to 3 is recommended in patients with AF.

AF is a costly public health issue. A study analyzing three federally funded databases in the United States in 2005 suggested a total annual cost of US$6.65 billion for the treatment of AF, including US$2.93 billion (44 percent) for hospitalizations with a principal discharge diagnosis of AF, US$1.95 billion (29 percent) for the incremental inpatient cost of AF as a comorbid diagnosis, US$1.53 billion (23 percent) for outpatient treatment of AF, and US$235 million (4 percent) for prescription drugs.[11] In all analyses, AF was a significant contributor to hospital cost.

## INDICATIONS FOR SURGICAL ABLATION

The indications for surgical ablation have been defined in a recent consensus statement and include[5]:

1. All symptomatic patients with documented AF undergoing other cardiac surgical procedures
2. Selected asymptomatic patients with AF undergoing cardiac surgery in which the ablation can be performed with minimal risk in experienced centers
3. Stand-alone surgery should be considered for symptomatic patients with AF who either prefer a surgical approach, have failed one or more attempts of catheter ablation, or are not candidates for catheter ablation.

There is still controversy regarding the referral of patients for surgery with medically refractory, symptomatic lone AF in lieu of less invasive catheter ablation. In our opinion, there are relative indications for surgery that were not included or expressed in the consensus statement:

1. AF patients who develop a contraindication to long-term anticoagulation and have a high risk for stroke (CHADS score ≥2) are excellent candidates for surgery. The CMP not only is able to eliminate AF in most of these patients, but also amputates the left atrial appendage, which is known to be one of the main sources of atrial thrombus formation. The stroke rate following the procedure off anticoagulation has been remarkably low, even in patients with high CHADS scores.
2. Patients with longstanding AF who have suffered a cerebrovascular accident despite adequate anticoagulation are at high risk for repeat neurological events. In our experience of over 200 patients with a stand-alone CMP, there was only one late stroke, with over 80 percent of patients off anticoagulation at last follow-up. This is remarkable in that about 20 percent of patients had experienced at least one cerebrovascular accident before surgery.
3. AF patients with a clot in the left atrial appendage are not candidates for catheter ablation and should be considered for surgical ablation.

In the era of minimally invasive approaches, including thoracoscopic and hybrid procedures, a team approach including both electrophysiologists and surgeons should be established to ensure appropriate patient and treatment selection.

## ELECTROPHYSIOLOGICAL EVALUATION AND DIAGNOSTIC MODALITIES

It has not been possible to locate the precise mechanism of AF in the majority of patients prior to surgery due to the limitations of endocardial non-contact mapping and the invasiveness of epicardial mapping. Traditional epicardial activation sequence mapping is difficult and time-consuming and has not been suitable to provide useful real-time information during the procedure. Improvements in technology and further experimentation may provide the means for faster data analysis; a map-directed approach may be feasible in the future. Electrocardiographic imaging (ECGI) can be used to compute epicardial potentials noninvasively and reconstruct a 3-dimensional anatomical map of atrial electrical activity using multiple surface electrodes and anatomic data obtained through CT.

Besides documentation of the patient's heart rhythm prior to surgery, a preoperative transthoracic and an intraoperative transesophageal echocardiogram should be performed to determine the left atrial diameter and to evaluate for the presence of a left atrial thrombus. Left atrial size is a significant predictor of failure in our series and is important to define prior to surgery.[12] It is our policy that in patients with a left atrial size ≥7 cm, a left atrial reduction procedure should be considered. A cardiac catheterization will provide information about the presence of coronary artery disease. Moreover, the anatomical location of the circumflex coronary artery is important to define in order to safely perform the left atrial isthmus lesion and the ablation of the coronary sinus. In patients who have failed catheter ablation, a chest CT is indicated to assess for PV stenosis. It is also important to determine the precise atrial tachyarrhythmia in patients who have failed catheter ablation; that may require an electrophysiological study. Atrial tachycardia is usually not

amenable to surgical ablation and atypical atrial flutter usually necessitates a full Cox-Maze lesion set.

## DEVELOPMENT OF THE COX-MAZE PROCEDURE

In 1987, Dr. James Cox introduced the Maze procedure for the surgical treatment of AF at Washington University in Saint Louis. Following extensive experimental investigation, his surgical approach was designed to block the multiple macroreentrant circuits which were believed to be the cause of AF.[13] Unlike other historical attempts to address AF, such as the left atrial isolation procedure, His bundle ablation, the corridor procedure, or the atrial transection procedure, the CMP successfully restored both AV synchrony and sinus rhythm, thus potentially reducing the risk of thromboembolism and stroke. The operation consisted of creating surgical incisions in both the right and left atria. These incisions were placed in a pattern that allowed the propagation of the sinoatrial node impulse throughout both atria (Fig. 43-2A). This resulted in a preserved activation of most of the atrial myocardium, resulting in preservation of atrial transport function in most patients.

The original version, the *CMP I*, was modified due to problems with late chronotropic incompetence and a high incidence of pacemaker implantations. The *CMP II* was technically difficult to perform and was soon replaced by the final iteration known as the *CMP III* (Fig. 43-2B).[14] The CMP III, often referred to as the "cut-and-sew" Maze, became the gold standard for the surgical treatment of AF with excellent long-term success rates and a low postoperative risk of stroke.[15] In our series at Washington University, 97 percent of 198 consecutive patients who underwent this procedure with a mean follow-up of 5.4 years were free from symptomatic AF. There was no difference in success rates between patients undergoing a stand-alone CMP and those undergoing concomitant procedures and it was also equally efficacious in paroxysmal and persistent or longstanding persistent AF.[15]

Despite its proven efficacy, the CMP III was technically challenging and invasive, and few cardiac surgeons still perform this operation today. At most centers, the surgical incisions have been replaced with linear lines of ablation using a variety of different energy sources. These ablation-assisted procedures have greatly expanded the field of AF surgery in the last decade. With present ablation technology, surgery can be performed with low mortality and limited access incisions while preserving the high success rates of the traditional procedure.

In our laboratory, bipolar radiofrequency (RF) energy was found to be able to create reliable transmural lines of ablation on the beating heart in seconds while minimizing the risk of collateral damage to the surrounding tissue.[16,17] Since the energy is applied within the jaws of a clamp, it is inherently safer than unipolar sources.[18] It has been used successfully to replace most of the surgical incisions of the CMP III procedure. In 2002, the authors' group introduced an ablation-assisted procedure, termed the CMP IV, which has now been performed in almost 400 patients.

## SURGICAL ABLATION TECHNOLOGIES

The development of alternative energy sources to create transmural lines of ablation has revolutionized the field of antiarrhythmic surgery, making the procedures less time-consuming, easier to perform, and amenable to minimally-invasive approaches.

Several important criteria must be met by the chosen ablation technology to be considered as a replacement of surgical incisions: It must reliably produce bidirectional conduction block since this is the mechanism by which incisions either block macro- and microreentrant circuits or isolate trigger foci. Our laboratory has shown that this requires a completely transmural lesion, as even small gaps as narrow as 1.5 mm within ablation lines can conduct fibrillatory impulses. The second crucial characteristic of an ablation device is its safety. This requires a precise definition of dose–response curves to

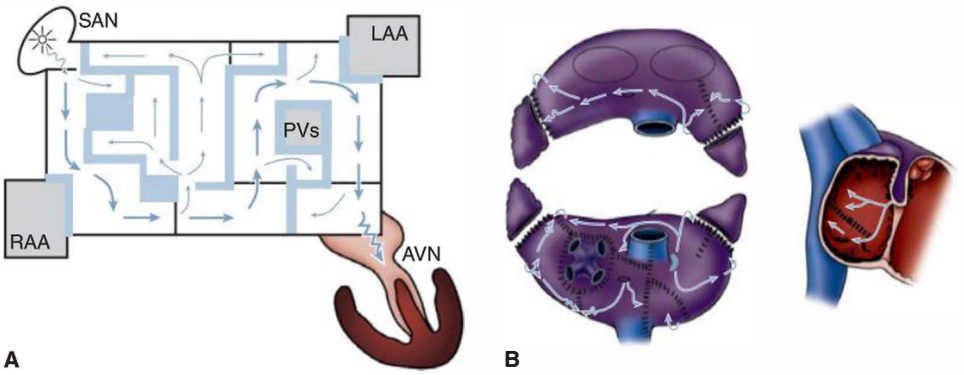

**FIGURE 43-2** **A.** Propagation of the sinus impulse throughout both atria in the original Cox-Maze procedure. **B.** The original cut-and-sew Cox-Maze procedure III. Copyright Mosby.)

limit excessive or inadequate ablation. The surgeon must also have knowledge of the effects of the specific ablation technology on surrounding vital cardiac structures, such as the coronary sinus, coronary arteries, valvular structures, such that the risk of collateral damage to surrounding extracardiac structures, like the esophagus or the phrenic nerve, is minimized. Third, a device should make AF surgery simpler, require less time to perform, and allow for a minimally invasive or endoscopic approach. This would require features such as rapidity of lesion formation, simplicity of use, adequate length and flexibility, and the ability to reliably create transmural lesions epicardially on the beating heart. Currently, no device has perfectly met all of these criteria.

It is necessary to understand the variability of human atrial wall thickness to define the performance of any epicardial ablation device. In normal individuals, the mean atrial thickness of the posterior left atrium (LA) between the PVs ranges from 2.3 ± 1.0 mm between the superior veins to 2.9 ± 1.3 mm between the inferior veins. In patients with a history of AF, the tissue is thinner, ranging from 2.1 ± 0.9 mm to 2.5 ± 1.3 mm. In both groups, the thickness increases, moving from the superior to the inferior veins. In normal individuals, the thickness in the LA just above the coronary sinus is 6.5 ± 2.5 mm. The thickness of Bachmann's bundle, a preferential conduction pathway between the right and left atria crossing across the roof of the atria in the transverse sinus, is 4.6 ± 1.1 mm (range: 1.7–9.3 mm) in normal individuals.

In patients with structural heart disease, reflecting more closely those patients referred for surgical ablation, the mean LA thickness is 5.2 ± 1.8 mm (range: 3–15 mm). The crista terminalis in the RA has an average thickness of 7.7 ± 2.4 mm (range: 4.2–12.6 mm). This has to be considered when comparing these patients to those treated by electrophysiologists in the catheterization laboratory without concomitant cardiac pathology. This wide range of wall thickness does not take into account overlying fat or underlying free running pectinate muscles. Even in normal individuals, the fat layer at the posterior mitral annulus can be 10 mm thick. Epicardial fat is a barrier to depth of penetration for most ablation technologies. In addition, there are free-running pectinate muscles in both the right and left atria that are not continuous with the epicardial surface. As patients grow older, their chamber size and wall thickness increase. This highly variable wall thickness and anatomy provide a challenge to any unidirectional device attempting to achieve transmural lesions.

The following sections will briefly summarize the current ablation "…technologies, including their advantages and disadvantages.

## Cryoablation

Cryoablation has been used to ablate arrhythmias for over 3 decades and has the benefit of preserving fibrous tissue and collagen. Because of this, it has been one of the safest energy sources available. As opposed to other alternative energy sources, cryoablation creates direct physical injury, a cumulative sublethal cellular stress response, and molecular-based cell death by freezing instead of heating. The formation of intracellular and extracellular ice crystals disrupts the cell membrane and causes cell death. A homogenous surface contact is essential for good ablation performance. Any fluid or vapor trapped between the probe and the targeted tissue freezes to form ice balls. Ice has a low thermal conductivity coefficient and increases thermal resistance. Thus, ice ball formation within the valleys of a nonuniform surface acts as an insulator, retarding heat loss. The onset of ice formation at the cryoprobe provides cryo-adhesion to maintain and ensure tissue contact and creates an area at which heat is extracted from the tissue. As heat is removed by various cryogens such as nitrous oxide or argon, extracellular fluid freezes at −20°C, creating a hyperosmotic environment that causes cell shrinkage and ultimately cell death.[19] Rapid freezing to −40°C induces expansion of intracellular ice formation that disrupts organelles and cell membranes even before osmotic imbalance occurs. A fast rate of cooling will increase cell death, while slowly thawing the tissue is also effective in prolonging the mechanisms of cell destruction.[19] Currently, two commercially available sources of cryothermal energy are being used in cardiac surgery. One is manufactured by AtriCure (Cincinnati, OH) and uses a disposable malleable linear probe or reusable rigid probes with nitrous oxide as the cooling agent. More recently, Medtronic (Minneapolis, MN) has distributed a malleable linear probe and a clamp device based on argon. At 1 atm of pressure, nitrous oxide is capable of cooling tissue to −89.5°C, while argon can reach a temperature of −185.7°C. Cryoablation has a well-defined efficacy and safety profile and is generally safe except around the coronary arteries. The relatively long time period of 1 to 3 min required to reliably create transmural lesions is one potential disadvantage of cryoablation. There is also difficulty in creating lesions on the beating heart due to the "heat sink" of the circulating blood. Furthermore, if blood is frozen during epicardial ablation on the beating heart, it coagulates, creating a potential thromboembolic risk.

## Radiofrequency Energy

RF energy has been used for cardiac ablation for many years in the electrophysiology laboratory, and was one of the first energy sources to be applied in the operating room. RF energy uses alternating current in the range of 100 to 1000 kilohertz (kHz). This frequency is high enough to prevent rapid myocardial depolarization and the induction of ventricular fibrillation, yet low enough to prevent tissue vaporization and perforation. The lesion size created by thermal injury depends on electrode–tissue contact area, the interface temperature, the current and voltage (power), as well as the duration of delivery. On histologic evaluation of radiofrequency lesions, a focal coagulation necrosis predominates acutely. This correlates with the irreversible nature of the injury, which occurs at temperatures greater than 50°C.

There is destruction of the myocardial collagen matrix and replacement with fibrin and collagen in chronic studies. At very high temperatures greater than 100°C, char formation predominates. Char is an impediment to heat transduction and has been associated with asymmetrical ablations. The depth of the lesion can be limited by char formation, epicardial fat, myocardial and endocavity blood flow, and tissue thickness. Resistive RF energy can be delivered by either *unipolar* or *bipolar* electrodes.

Numerous *unipolar RF* devices are currently on the market with popular devices distributed by Estech (San Ramon, CA), nContact (Raleigh, NC), and Medtronic (Minneapolis, MN). These include both dry and irrigated devices as well as devices which incorporate suction in an attempt to improve tissue surface contact. Resistive heating occurs only within a narrow rim of tissue in direct contact with the electrode, usually less than 1 mm. The deeper tissue heating occurs via passive conduction. To prevent char formation at the tissue–electrode interface, irrigated catheters were developed to keep temperatures cooler at the tissue interface. These irrigated catheters have been shown to create larger volume lesions than dry RF devices. While in animals, unipolar RF has been shown to create transmural lesions on the arrested heart with sufficiently long ablation times of 60 to 120 s; this has been more difficult in humans. After 2-minute endocardial ablations during mitral valve surgery, only 20 percent of the in vivo lesions were transmural. Epicardial ablation has been even more difficult. Animal studies have consistently shown that unipolar RF is incapable of creating epicardial transmural lesions on the beating heart. A recent clinical study confirmed this problem. Epicardial RF ablation in humans resulted in only 7 percent of lesions being transmural despite electrode temperatures of up to 90°C, which has been felt to be caused by the heat sink.[20] The complications of unipolar RF devices have been described after extensive clinical use and include coronary artery injuries, cerebrovascular accidents, and the devastating creation of esophageal perforation leading to atrial–esophageal fistula.

*Bipolar RF* technology is incorporated into devices in two ways. In one, the electrodes are embedded in the jaws of a clamp to focus the delivery of energy. Shielding the electrodes from the circulating blood pool, allows for faster ablation times and limits collateral injury to surrounding structures. The second way it is used is in a linear device in which the two electrodes are side-by-side and the device is applied to either the epicardial or endocardial surface. Bipolar RF ablation clamps are the most reliable devices for creating transmural lesions on the beating heart both in animals and in humans with short ablation times.[16,21,22] The linear pens developed for epicardial ablation on the beating heart have not been as reliable and, in a study from our laboratory, were not successful at creating linear lines of block in experimental models. Three companies (AtriCure, West Chester, OH; Medtronic, Minneapolis, MN; and Estech, San Ramon, CA) currently market bipolar RF devices. Use of the bipolar RF clamp devices have eliminated most of the collateral damage that occurred with the unipolar devices. This is likely due to the focused delivery of energy within the jaws of the clamp, eliminating the diffuse radiation of heat. However, the devices with side-by-side bipolar electrodes have not been extensively evaluated for safety yet and would have the same potential problems as unipolar devices.

## High-Intensity Focused Ultrasound

High-intensity focused ultrasound (HIFU) is another modality being applied clinically for surgical ablation (St. Jude Medical, St. Paul, MN). Ultrasound effectively ablates tissue via mechanical hyperthermia. When ultrasound waves are emitted from the transducer, the resulting wave travels through the tissue causing compression, refraction, and particle movement. This translates into kinetic energy and ultimately thermal coagulative tissue necrosis. HIFU produces rapid, high-concentration energy in a focused area, and is reportedly able to create transmural epicardial lesions through epicardial fat in a short time.[23]

HIFU is unique in that it is able to create noninvasive, noncontact focal ablation in 3-dimensional volume without affecting intervening and surrounding tissue. It utilizes ultrasound beams in the frequency range of 1 to 5 megahertz (MHz) or higher, creating focused lesions quickly by rapidly raising the temperature of the targeted tissue to above 80°C, effectively causing cell death. By focusing ultrasound waves, HIFU is able to create targeted thermal coagulation of tissue at a very well-defined focus without harming intervening tissue. Its ability to focus the target of ablation at specific depths is an advantage over other energy modalities. Another advantage of HIFU technology is its mechanism of thermal ablation. Unlike all other energy sources that heat or cool tissue by thermal conduction, HIFU ablates tissue by directly heating the tissue in the acoustic focal volume, and is therefore much less affected by the "heat sink" of the circulating endocardial blood pool. The clinical studies utilizing HIFU have had mixed results.[23] There has been little independent experimental verification of the efficacy of HIFU devices to reliably create transmural lesions and long-term efficacy seems to be rather disappointing. The fixed depth of penetration of these devices may be a major problem in the wide range of thickness of pathologically altered atrial tissue.

In summary, each ablation technology has its own advantages and disadvantages. In the future, it will be imperative for surgeons to develop a more complete understanding of the effects of each surgical ablation technology and more carefully consider variations in atrial anatomy and electrophysiology. The effect of the applied technology on vital structures and on atrial function needs to be better delineated. This will allow for more appropriate use of devices in the operating room for each individual patient. While most of the devices have been shown to be efficacious in the arrested heart, few have shown the capability of creating reliable transmural lesions on the beating heart. This has to be considered in the era of the development of endoscopic and hybrid approaches attempting to evoke less invasive surgical ablation techniques.

## SURGICAL TECHNIQUES AND OUTCOMES

There are a variety of surgical procedures currently performed to ablate AF. They can be grouped into three broad categories: the biatrial CMP, left atrial lesion sets, and PVI.

Recently, new approaches have been developed for the treatment of lone AF. Epicardial lesions performed on the beating heart, including PVI and left atrial lesion sets, allow for an endoscopic approach without the need for cardiopulmonary bypass. Furthermore, a hybrid team approach with electrophysiologists applying endocardial catheter ablation techniques combines the promising success rates of epicardial surgical ablation with more sophisticated mapping to determine lesion integrity and evaluate results.

### The Cox-Maze IV Procedure

The CMP-IV can be performed through either a median sternotomy or a minimally invasive right minithoracotomy.[24] After initiating normothermic cardiopulmonary bypass, the right and left PVs are bluntly dissected. If the patient is in AF, amiodarone is administered and the patient is electrically cardioverted after a left atrial thrombus is ruled out by intraoperative transesophageal echocardiography. Pacing thresholds are obtained from each PV. Using a bipolar RF ablation device, the PVs are isolated by ablating a cuff of surrounding atrial tissue. Proof of electrical isolation is confirmed by demonstrating exit and/or entrance block from each PV.

The right atrial lesion set is performed on the beating heart (Fig. 43-3A). A single incision is usually made in the right atrial free wall, but recently a three-purse-string approach has been adopted to eliminate this incision in patients undergoing a minithoracotomy approach. All ablations are performed with the bipolar RF clamp except for two endocardial ablation lines to the tricuspid annulus. These are performed endocardially with a linear cryoprobe that is cooled to −60°C for 2 to 3 min.

The left-sided lesion set is performed via a standard left atriotomy under cardioplegic arrest (Fig. 43-3B). Our group has shown that isolating the entire posterior left atrium with connecting ablation lines between the upper and lower PVs, termed the box lesion set which resembles more closely the original CMP-III lesion set, resulted in a significantly higher drug-free freedom from AF at 6 and 12 months.[24] Cryoablation is used to connect the lesion to the mitral annulus and complete the left atrial isthmus line. It is important to remember that the coronary sinus needs to be ablated in line with the endocardial ablation in order to create the left atrial isthmus line. This is usually done with either the bipolar RF clamp or a linear cryoprobe placed epicardially over the coronary sinus. The left atrial appendage is amputated, and a final ablation is performed through the amputated left atria appendage into one of the left PVs. In patients undergoing a right minithoracotomy, cryoablation is more extensively applied to complete the posterior left atrial isolation and the left atrial appendage is oversewn from the inside.

#### OUTCOMES

A propensity analysis performed by our group has shown that there was no significant difference in the freedom from AF at 3, 6, or 12 months between the CMP III and IV groups.[25] However, the CMP IV has significantly shortened operative time and lowered complication rates while maintaining the high success rate of the original CMP III.[25,26] A Kaplan–Meier estimate of freedom from symptomatic AF for our entire CMP series was 85 percent at 10 years (Fig. 43-4). In 100 patients undergoing a stand-alone CMP-IV for lone AF (31 percent paroxysmal and 69 percent persistent or longstanding persistent AF), freedom from AF was 90 percent and freedom from AF off antiarrhythmic medication was 84 percent at 2 years with no intraoperative mortality and no postoperative strokes (Fig. 43-5).[27] Moreover, 84 percent of patients were free from anticoagulative therapy with warfarin. Failure was strictly defined in accordance with the recent consensus statement, whereby over two-thirds of

patients had prolonged monitoring. In the entire CMP IV series, including concomitant cardiac procedures, the freedom from AF was 89 percent and the freedom from AF off antiarrhythmic drugs was 78 percent at 1 year.[12] There was also no difference in success rates for patients with paroxysmal compared with persistent or longstanding persistent AF.[12,27] An enlarged left atrial diameter, failure to isolate the entire posterior atrium with a complete box lesion set, and early atrial tachyarrhythmias were the predictors identified for late AF recurrence.

## Left Atrial Lesion Sets

Over the past decade, there have been a number of new surgical procedures introduced in an attempt to surgically treat AF. These procedures have generally involved some subset of the left atrial lesion set of the CMP. The results have been variable and have ranged from 20 to 90 percent rates of freedom from AF. They have been dependant on the technology used, the lesion set, and the patient population.

### OUTCOMES

A number of centers around the world have suggested performing ablation confined to the left atrium only to cure AF. This concept is supported by the fact that the majority of paroxysmal AF appears to originate around the PVs and the posterior left atrium. A left atrial lesion set typically involves PVI with an isthmus lesion to the mitral annulus as well as removal of the left atrial appendage. A myriad of ablation technologies has been used to create these lesion sets with a varied degree of success. There have been no randomized trials of biatrial versus left atrial ablation in the surgical population. Because of this, the importance of the right atrial lesions of the traditional CMP is difficult to determine. A meta-analysis of the published literature by Ad and colleagues revealed that a biatrial lesion set resulted in a significantly higher late freedom from AF when compared with a left atrial lesion set alone (87 vs 73 percent, $p = 0.05$).[28] This is not surprising considering the results of intraoperative mapping of patients with AF, showing that AF can originate from the right atrium in up to one-third of patients. In a rare randomized trail, Gaita and colleagues examined PVI alone versus two alternate left atrial lesion sets that both included an isthmus line. In this study, normal sinus rhythm at 2-year follow-up was only seen in 20 percent in the PVI group versus 57 percent in the other groups ($p < 0.006$).[29] Finally, our group has shown that isolating the entire posterior left atrium significantly improved drug-free freedom from AF at 6 months (54 vs 79 percent, $p = 0.011$) in a retrospective analysis.

## Pulmonary Vein Isolation—The Thoracoscopic Approach

PVI is an attractive therapeutic strategy because the procedure can be done without cardiopulmonary bypass and with minimally invasive techniques, utilizing either endoscopic approaches or small incisions. Based on the original report of Haïssaguerre, it has been documented that the triggers for paroxysmal AF originate from the PVs in many patients with lone AF. However, it important to remember that up to 30 percent of triggers may originate outside the PVs. This might be even more often the case in patients with structural heart disease. The PVs can be isolated separately or as a box. The most common technique described here utilizes an endoscopic, port-based approach to minimize incisional size and pain for the patient. At our institution, bipolar RF

clamps are favored to isolate the PVs, but unipolar RF and HIFU devices have been used as well.

Patients are intubated with a double-lumen endotracheal tube and external defibrillator pads are placed. A transesophageal echocardiogram is performed to confirm the absence of thrombus in the left atrial appendage. If a thrombus is found, the procedure is either aborted or converted to an open procedure, where the risk of systemic thromboembolism from left atrial clot can be minimized. An initial port for the thoracoscopic camera is usually placed at the fifth intercostal space. Under thoracoscopic vision, two small working ports can then be placed in the fourth and sixth intercostal spaces along the midaxillary line (Fig. 43-6). Under single-lung ventilation, the right phrenic nerve is identified and the pericardium is opened anterior and parallel to the phrenic nerve to expose the heart from the superior vena cava to the diaphragm. The space above and below the right PVs is dissected to allow enough room for insertion of an articulating dissector. The dissector and a guiding sheath are introduced and guided into the space between the PVs and the right pulmonary artery. After the dissector is removed, the sheath remains in place as a guide for the insertion of the bipolar RF clamp. At this point, the patient is cardioverted into sinus rhythm if needed so that pacing thresholds can be obtained. It is critically important to document entrance and/or exit block after ablation to confirm PVI. Some surgeons also use the opportunity provided by surgical exposure to detect and ablate ganglionic plexi (GP) at this time. High-frequency stimulation evokes a vagal response with bradycardia when applied to GP. The detected areas can be ablated until the vagal response diminishes. After pacing maneuvers are completed, the sheath is attached to the lower jaw of a bipolar RF clamp. The clamp is introduced into the chest, and the veins are clamped and ablated.

The approach to the left chest is similar to that to the right. The ports are positioned slightly more posterior than on the right side. The left phrenic nerve is identified, and the pericardium is opened posterior to the course of the nerve. The Ligament of Marshall is identified and divided. The dissector is then introduced and the guiding sheath is used to position the RF clamp around the left PVs as described above. After isolation, exit and/or entrance block is confirmed with pacing.

A major advantage of surgery is that the left atrial appendage can be addressed as well. This has been done by stapling across the base of the left atrial appendage with an endoscopic stapler or by placing an appendage-occluding device. After ablation of the left PVs and exclusion of the left atrial appendage, the left side of the pericardium must be closed to avoid herniation of the heart.

**FIGURE 43-6** Thoracoscopic port positioning for minimally-invasive pulmonary vein isolation.

### OUTCOMES

The results of PVI alone have been variable and dependent on patient selection. Different studies have shown encouraging results in patients with paroxysmal AF. Reports suggest a success rate between 80 and 89 percent in those patients after PVI. However, success rates decrease substantially in patients with persistent or longstanding persistent AF. Edgerton and colleagues reported only 56 percent of patients with persistent AF being free from AF at 6 months after PVI, with merely 35 percent being both free from AF and antiarrhythmics.[30] With concomitant procedures, the success rate of PVI is even worse. This is not surprising because those patients present with different underlying mechanisms for AF and a choice for PVI as a treatment option seems to be insufficient in most of those patients. There have been no randomized trials establishing the efficacy of GP ablation in increasing durable success rates. At our institution, we do not perform or recommend GP ablation. This is due to the lack of supporting data and the fact that our laboratory has shown reinnervation just 1 month following GP ablation in an experimental model.

## Thoracoscopic Left Atrial Lesion Set

There is wide consensus that the goal of developing less invasive procedures should not be at the cost of success rates. To address the shortcomings of PVI alone in many patients, new ablation devices have been developed allowing for an extension of the applied lesion set that can be performed thoracoscopically. Using a new generation of bipolar and unipolar RF devices, it is possible to perform a more extensive left atrial box lesion set epicardially through port access. In addition to the PVI technique described above, the transverse and oblique sinuses are dissected. This allows for a box lesion set to be performed isolating not just the PVs but the entire posterior left atrium. It is crucial that attention is paid to overlapping the lines of ablation from the right and the left side to avoid gaps and to complete a transmural roof lesion. An inferior line is created to connect the encircling ablation of the inferior right PV with that of the inferior left PV. Because it is impossible to perform a left atrial isthmus line epicardially, it is recommended to add a trigonal line of ablation from the

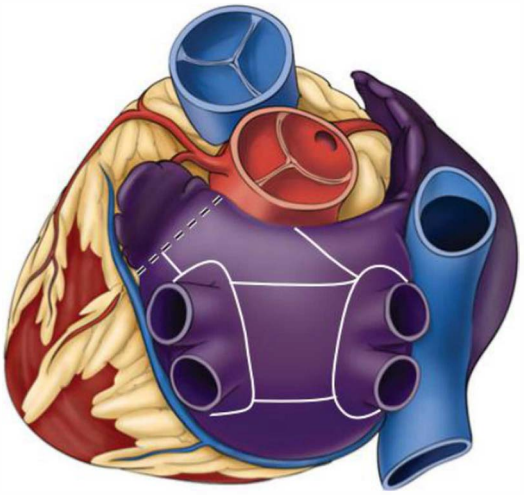

FIGURE 43-7 Endoscopic approach with extended left atrial lesion set.

isolated superior right PV to the aortic annulus (Fig. 43-7). To confirm conduction block of the ablation lines, pacing should be performed from within the box.

### OUTCOMES

Early results with an extended left atrial lesion set in addition to PVI have shown improved success, especially in patients with persistent AF compared with PVI alone. Sirak and colleagues reported a success rate of 87 percent off antiarrhythmic drugs after 6 months in 32 patients with persistent AF. In a larger series of almost 50 patients, Weimar and co-workers achieved success rates of about 90 percent freedom from AF and 85 percent freedom from AF off drugs at 12 month follow-up, independent of the type of AF, with no intraoperative complications or conversion to sternotomy. However, it is important to point out that it is technically challenging and more time-consuming to perform these extended lesions thoracoscopically and that proof of conductance block is mandatory for the box lesion set as well. This necessity to prove lesion integrity is due to the fact that there are still no devices on the market that reliably create linear transmural lesions on the beating heart except for the bipolar clamps. Also, it is important to note that acute demonstration of conduction delay or block does not guarantee a chronic block or transmural lesion. Demonstration of conduction delay can be difficult and may lead to misinterpretation even by experienced surgeons and electrophysiologists.

## The Hybrid Approach

The goal of the hybrid procedure is to combine the benefits of epicardially performed surgical ablation and endocardially performed catheter ablation in a dual approach. While thoracoscopic surgery is effective in isolating the PVs, addressing the Ligament of Marshall and managing the left atrial appendage, it has its limitations in effectively ablating atrial tissue, particularly the right and left atrial isthmus and the coronary sinus. Those areas can be addressed by catheter ablation if intraoperative mapping performed by the electrophysiologist shows gaps and conduction in one or more of these regions. Also, the success of creating transmural ablation lines can be confirmed by instantaneous mapping and by demonstrating conduction block using pacing. Possible gaps can then be closed by endocardial catheter ablation in the same setting (Fig. 43-8). Ideally, this procedure should be performed in a hybrid operating room. Because the underlying pathologic mechanisms are more complex in patients with persistent AF, this team approach may allow for a more patient-tailored

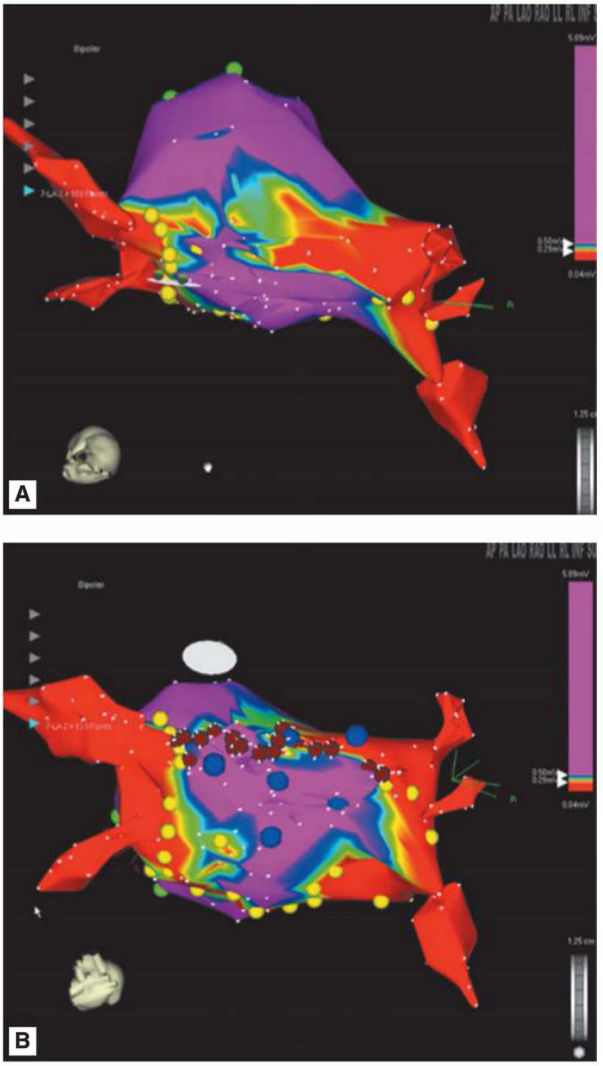

FIGURE 43-8 Intraoperative mapping during a hybrid procedure. **A.** Demonstration of gaps at the roof line after surgical ablation. **B.** Mapping after endocardial catheter ablation with closed gaps.

lesion set that more effectively prevents AF recurrence. A recent study from Allessie and colleagues has formed what they call the "Double Layer Hypothesis," where narrow wavelets in the endocardial and epicardial layers of the heart constantly feed each other in persistent AF. Although this has to be confirmed by further studies, it could add further support as to why hybrid ablation might be a promising approach for persistent AF.

### OUTCOMES

Only a few centers have reported on hybrid procedures. In many institutions it has been challenging to set up a team approach involving both electrophysiologists and surgeons. Edgerton and colleagues presented data on 12 patients with persistent AF who received hybrid ablation at the University of Virginia and University of Maastricht. At 12 month follow-up, 83 percent of patients were free from AF and off antiarrhythmic drugs. It is too early to comment on the efficacy or safety of the hybrid approach. Scientifically conducted trials are needed to evaluate any advantage over other ablation strategies.

## SUMMARY

In conclusion, the development of ablation technologies has dramatically changed the field of AF surgery. The replacement of the surgical incisions with linear lines of ablation has transformed a complex, technically demanding procedure into one accessible to the majority of surgeons. More importantly, these new ablation technologies have introduced the possibility of minimally invasive surgery for AF, prompting numerous efforts to develop simpler procedures that can be performed epicardially on the beating heart. There is already strong evidence that PVI may be effective in a subset of patients with paroxysmal AF. With extended lesions sets, it may be possible to extend the efficacy of minimally invasive procedures to patients with persistent and longstanding AF. However, surgeons must remember that the CMP has excellent efficacy in these patients and can be performed using a minithoracotomy with excellent success and low morbidity. It is imperative for surgeons who develop new procedures or lesion sets to carefully follow their results and to publish them in peer-reviewed journals. It also is mandatory to adhere to the recently published guidelines for follow-up of patients and for determining success or failure after these procedures. The biatrial CMP with 90 percent success rates in all types of AF still sets the benchmark for alternative lesion sets as well as for new and less invasive approaches currently under development.

## SURGICAL THERAPIES FOR ATRIAL FIBRILLATION BOARD REVIEW QUESTIONS (CHAPTER 43)

1. Which is not a component of atrial fibrillation?
   A. A trigger
   B. Disordered AV nodal tissue
   C. Effective refractory period
   D. Conduction velocity
   E. Atrial anatomy

2. Which is correct regarding mechanisms of atrial fibrillation?
   A. Premature beats that trigger AF are only located in the pulmonary veins about 50 percent of the time.
   B. The conduction velocity within the pulmonary veins is faster than surrounding atrial tissue.
   C. The complex fiber orientation travels parallel within the pulmonary veins.
   D. Circus movement reentry is characterized by an activation that travels through the orifice of the pulmonary veins.
   E. Leading circle reentry requires an anatomic obstacle for the circuit.

3. Which is not associated with atrial fibrillation?
   A. Hypertension
   B. Aortic aneurysm
   C. Congestive heart failure
   D. Valvular heart disease
   E. Ischemic heart disease

4. Which of the following is not an indication for surgical ablation?
   A. A symptomatic patient with atrial fibrillation undergoing another cardiac surgical procedure
   B. An asymptomatic patient with atrial fibrillation undergoing another cardiac surgical procedure
   C. Stand-alone surgery after two failed catheter ablations
   D. A patient with atrial fibrillation and a left atrial appendage thrombus
   E. A patient with a contraindication to long-term anticoagulation and a CHADS score of 3

5. Which is true regarding outcomes after surgery for atrial fibrillation?
   A. Long-term freedom from AF after Cox-Maze IV for lone AF is 80 percent.
   B. One-year freedom from AF after Cox-Maze IV off antiarrhythmic medications is 80 percent.
   C. A biatrial lesion set does not improve late freedom from AF.
   D. Isolation of the entire posterior left atrium does not improve drug-free freedom from AF.
   E. Freedom from AF after PVI for paroxysmal AF ranges between 65 and 80 percent.

## ANSWERS

1. **Answer: B.** Atrial fibrillation requires both an initiating event (a trigger) and a permissive atrial substrate (altered refractory period, conduction velocity, or atrial anatomy). Disordered AV nodal tissue is not a component of atrial fibrillation.

2. **Answer: A.** Only 50 percent of triggers are found in the pulmonary veins. The conduction velocity within the pulmonary veins is slower than surrounding atrial tissue. The complex fiber orientation spirals perpendicularly around the veins. Circus movement reentry is characterized by an activation that travels around an anatomic structure. Leading circle reentry does not require an anatomic obstacle.

3. **Answer: B.** Hypertension, congestive heart failure, valvular heart disease, and ischemic heart disease are all associated with atrial fibrillation. Isolated aortic aneurysm is not associated with atrial fibrillation.

4. **Answer: D.** Presence of a left atrial appendage thrombus is not an indication for surgery. Any symptomatic or asymptomatic patient with atrial fibrillation undergoing another cardiac surgical procedure should be considered for concomitant surgical ablation. Stand-alone surgery should be considered in patients after one or more failed catheter ablations. A patient with a CHADS score of 2 or greater with a contraindication to anticoagulation should be considered for surgical ablation.

5. **Answer: B.** One-year freedom from AF after Cox-Maze IV off antiarrhythmic medications is 80 percent. Long-term freedom from AF after Cox-Maze IV for lone AF is 90 percent. A biatrial lesion set and isolation of the entire posterior left atrium both significantly improve late freedom from AF. Freedom from AF after PVI for paroxysmal AF ranges between 80 and 90 percent.

# Pacemaker and Defibrillator Therapy in Cardiac Surgery Patients

*Brad S. Sutton*
*Kenneth C. Bilchick*
*Ronald D. Berger*

**KEY CONCEPTS**

- Pacemaker therapy effectively treats bradycardia-related symptoms for patients with sinus node dysfunction, advanced atrioventricular (AV) block, and in some instances carotid sinus hypersensitivity.
- Conduction disturbance after cardiac surgery is relatively common after coronary artery bypass grafting and valve surgery. Although the natural history of postoperative AV block is variable, the need for a permanent pacemaker (PPM) system is higher in those with preexisting electrocardiogram abnormalities, prolonged bypass time, and repeat procedures.
- Bradycardia after cardiac transplantation is usually temporary and far less common with bicaval anastomoses.
- In carefully selected heart failure patients, cardiac resynchronization therapy (CRT) has been shown to improve heart failure symptoms, quality of life, and reduce mortality.
- Several randomized clinical trials have demonstrated reduced infectious complications following permanent device implantation with empiric periprocedural antibiotic administration.
- When coronary sinus anatomy or pacing parameters prohibit transvenous lead placement for CRT, a number of techniques can be used to place epicardial leads. Robotic arm placement may reduce the amount of postoperative pain that patients experience.
- Optimal PPM therapy requires selection of appropriate pacemaker type and pacing mode for each patient.
- Pacemaker complications can be divided into those associated with the implantation procedure, subsequent infections, loss of lead integrity, and programming-related problems.
- Indications for device extraction include systemic infection, arrhythmia or other complications related to retained fragments or leads, and the need for additional vascular access.
- Implantable cardioverter-defibrillator therapy is indicated for patients with structural heart disease and life-threatening ventricular arrhythmias or risk factors for sudden death.

## INTRODUCTION

Permanent pacemakers (PPMs) were introduced in the 1950s for use in patients with pathologic conditions of the sinus node, atrioventricular (AV) node, or His–Purkinje system. Since that time they have been refined to allow more complex programming. In addition, periprocedural morbidity has been reduced significantly. As a result, the number of devices implanted has increased steadily, with over 150,000 new pacemakers implanted in the United States each year.[1]

## ANATOMY OF THE CONDUCTION SYSTEM

The sinus node is an oval piece of tissue in the roof of the right atrium that is 10 to 20 mm long and 2 to 3 mm wide. It is less than 1 mm from the epicardial surface between the superior and inferior venae cavae.[2,3] Its blood supply is derived from the right coronary artery (RCA) 55 to 60 percent of the time and from the circumflex coronary artery 40 to 45 percent of the time.[2]

The atria are anatomically complex structures and differ significantly from each other. The right atrium is heavily trabeculated over the lateral wall and appendage and is characterized by significant heterogeneity, with abrupt changes in muscle fiber orientation over short distances. In contrast, the left atrium is a more uniform structure. Unlike ventricular myocardium, which contains Purkinje fibers, it now is generally accepted that the atria do not contain specialized conduction tissue. Instead, the spread of the impulse depends on the properties of the atrial muscle bundles. Simultaneous electrical mapping of canine left and right atria demonstrate that the left atrium consistently activates approximately 10 ms later than does the right atrium. Rapid activation of the anterior surface of the left atrium is facilitated by a muscle bundle known as Bachmann bundle. The wave fronts then converge in the posterior left atrium inferior to the pulmonary veins. Human atria demonstrate similar activation patterns, although the activation times are twice as long because of the larger atrial surface area.[3]

The compact portion of the AV node (AVN) is just beneath the right atrial endocardium anterior to the coronary sinus ostium and directly above the insertion of the septal leaflet of the tricuspid valve (TV). The AVN is located at the apex of the triangle of Koch, which is defined by the TV inferiorly, the tendon of Todaro superiorly, and a line drawn between the coronary sinus and the tricuspid annulus posteriorly. Of note, the node is well removed anteriorly from the coronary sinus. The AVN becomes the penetrating bundle of His at the central fibrous body. In 85 to 90 percent of people, the blood supply to the AVN is via the RCA; in the remainder, blood is supplied via the circumflex coronary artery.[2]

The branching portion of the His bundle begins at the muscular intraventricular septum and becomes the left

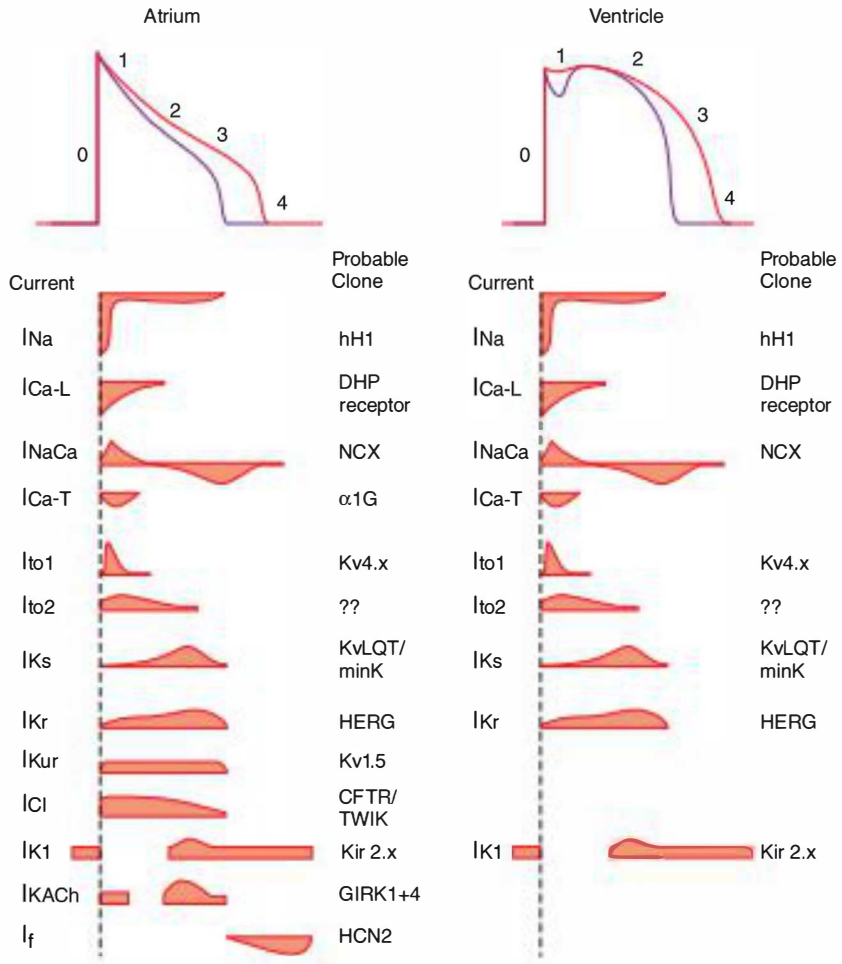

**FIGURE 44-1** Atrial and ventricular action potentials. Schematic of inward and outward ionic currents, pumps, and exchangers that underlie atrial and ventricular action potentials in the mammalian heart. Control and failing (*red line*) action potential profiles are shown on top. Each phase of the action potential is labeled. Under the action potentials, a schematic of the time course of each current is shown, and the gene product (probable clone) that underlies the current is indicated. (Reproduced with permission from Akar FG, Tomaselli GF. Genetic basis of cardiac arrhythmias. In: Fuster V, Alexander A, O'Rourke RA (eds). *Hurst's the Heart*, 11th ed. New York: McGraw-Hill, 2004.)

bundle branch (LBB) and the right bundle branch (RBB). The LBB arises and continues onto the septum beneath the noncoronary cusp of the aortic valve. The LBB may divide into anterior and posterior branches or may have a different branching pattern. The RBB continues as an unbranched extension of the AVN and continues along the right side of interventricular septum to the apex of the right ventricle (RV) and the base of the anterior papillary muscle. Purkinje fibers continue from the bundle branches as networks of conduction fibers on the endocardial surface of both ventricles.[2]

## ELECTRICAL PRINCIPLES OF CARDIAC PACING

The conducting tissues of the heart may be divided into fast-response and slow-response tissues. The distribution of ions and their associated electrical voltage gradients are responsible for the cardiac action potential. The baseline of this potential is −90 mV, and the peak is +20 mV for fast-response tissues (Fig. 44-1). The depolarization of fast-response tissues such as the atria, the bundle of His, bundle branches, and Purkinje fibers is due to an inward sodium current, whereas repolarization of those tissues is due primarily to outward potassium currents. In slow-response tissues such as the sinus node and the AVN, the baseline is about −70 mV and depolarization depends primarily on the L-type calcium current.

Cardiac pacing is based on the principle that myocardial cells can be depolarized repeatedly by electrical stimulation. In cardiac pacing, voltage is applied across two electrodes, at least one of which is in contact with myocardium. In bipolar leads, the two electrodes usually are separated from each other on the lead by about 1 cm. In unipolar leads, only one electrode is in contact with the myocardium, and the other electrode is typically the outer can of the pacemaker generator.

The voltage, current, resistance, and energy of a pacing system are related to one another according to the following equations:

$$V = I \times R$$

where $V$ = voltage (volts), $I$ = current (milliamperes), and $R$ = resistance (kilohms).

$$E = V \times I \times t \text{ (time the current is applied) or}$$
$$E = (V^2/R) \times t$$

Electrical sensing is based on the detection of the intrinsic current between the two electrodes on bipolar leads or between the lead tip and the pacemaker generator in a unipolar system, with a filter system in place. Unipolar systems are subject to much more noise and/or cross talk than are bipolar leads because the distance between the two electrodes is greater.

## CLINICAL INDICATIONS FOR PACING

### Indications for Permanent Pacing

Current indications for permanent pacing are based on the 2008 consensus guidelines published by the ACC/AHA/HRS.[4] The indications follow the standard evidence-based tiered system. A class I indication means that a procedure generally is agreed to be beneficial; class IIa indications are those for which there is conflicting evidence or a divergence of opinion but the weight of evidence is in favor of a procedure. Class IIb is similar to class IIa except that the efficacy of a procedure is less well established.

Permanent pacing should be considered for all patients with irreversible symptomatic bradycardia and selected patients with asymptomatic bradycardia. In addition, indications for cardiac resynchronization therapy (CRT) via biventricular pacing in patients with dilated cardiomyopathies have increased significantly in recent years. Pacing needs in specific cardiac operations are considered individually later in this section but are based on the general indications given below.

Common causes of symptomatic bradycardia include sinus node dysfunction (SND), third degree or advanced second degree AV block (AVB), and carotid sinus hypersensitivity (CSH). The following is a summary of the recommendations for PPM implantation in each of these conditions[4]:

- Class I recommendations for pacing in SND:
  - SND with documented symptomatic bradycardia
  - Symptomatic chronotropic incompetence
  - Symptomatic bradycardia that results from required drug therapy for medical conditions
- Class I recommendations for pacing in acquired AVB:
  - Third degree or advanced second degree AVB with symptomatic bradycardia
  - Third degree AVB that results from required drug therapy for medical conditions
  - AVB in symptom-free patients in sinus rhythm with asystole >3 s, escape rhythm <40 bpm, or infranodal escape
  - AVB in symptom-free patients in AF with pauses >5 s
  - Postoperative AVB that is not expected to resolve after surgery
  - Mobitz II second degree AVB
  - Alternating bundle branch block
- Class I recommendations for pacing for CSH:
  - Syncope occurring due to spontaneous CSH and carotid sinus pressure that induces ventricular asystole >3 s

### Permanent Pacing After Coronary Artery Bypass Grafting

After coronary artery bypass grafting (CABG) or valve surgery, patients may develop a number of conduction

disturbances, including a left hemiblock, right bundle branch block (RBBB), left bundle branch block (LBBB), bifascicular block, and AVB. The overall incidence of conduction disturbances after CABG is reported to be 10 to 15 percent.[5,6]. The significance of the various fascicular blocks after CABG has been controversial. In contrast to some early studies from the 1970s and 1980s, more recent studies of patients after CABG have not demonstrated any association between bundle branch block or intraventricular conduction defects and cardiac mortality over 3 to 5 years[7–9] even though these conduction disturbances probably indicate some degree of intraoperative myocardial damage.

It has been estimated that overall, 0.4 to 1.1 percent of patients who undergo CABG will require permanent pacing.[6] This risk is roughly doubled for patients undergoing repeat operations.[10] Risk factors for AVB and other conduction disturbances include advanced age, the number of vessels bypassed, left main coronary artery stenosis accompanied by total occlusion of a dominant RCA, the presence of an ungraftable RCA, proximal left anterior descending artery (LAD) stenosis involving the first septal perforator, aortic cross-clamp time, and prolonged hypothermic cardioplegia.[11–15] In one series of 120 consecutive cardiac surgery patients, the risk of postoperative pacemaker implantation was higher for patients with preexisting clinical or electrocardiogram (ECG) evidence of a conduction disturbance. In this study, predictors of long-term pacemaker dependency were postoperative complete AVB and bypass time >120 min.[16] Of note, the use of normothermic cardioplegia for shorter periods may be responsible for the decreased incidence of AVB after CABG in some series.[17]

The natural history of AVB in patients after CABG is that it may resolve within hours after the surgery; last for days, weeks, or months and then resolve; or persist.[11,12] In a series of 348 consecutive patients undergoing CABG, 56 of whom developed AVB postoperatively, the AVB lasted for less than 6 h in 32 (57 percent) and for more than 6 h in 24 (43 percent).[13] In another series of 93 consecutive patients undergoing CABG, all four patients who developed third-degree AVB after the operation were no longer in AVB after 2 months (AVB resolved in one patient on the second postoperative day; the other three patients had PPMs implanted before discharge).[11] Another study evaluated 26 patients who had a PPM implanted for AVB and 10 patients with a PPM implanted for SND after CABG. The pacemaker dependency rate (defined as the need for pacing with mode set to VVI 50) after 3 years was 65 percent for the AVB group and 30 percent for the SND group.[12] If the AVB resolves, permanent pacing is unnecessary. Although it may be reasoned that selected patients may not need a generator change at the time of battery end of life because of potential recovery of the conduction system, the authors generally maintain the PPM in most patients because it is difficult to establish with certainty that these patients will not require pacing at some point in the future. Furthermore, it should be noted that a generator change is a very low-risk procedure.

## Permanent Pacing After Valvular Surgery

Compared with the approximately 1 percent of patients undergoing CABG who have a need for permanent pacing, 3 to 6 percent of patients undergoing valve surgery require permanent pacing.[6,18] The most likely reason for the increased need for permanent pacing after valve surgery is the risk of trauma to the conduction system with this procedure. An estimation of the likelihood of the need for permanent pacing at the time of surgery informs the choice of the temporary epicardial pacing configuration. Since temporary leads may be associated with bleeding, tamponade, bypass graft injury, and infection, only the necessary number of leads should be implanted. For example, whereas a single ventricular epicardial lead may be appropriate for a low-risk patient, a dual-lead configuration with an additional ventricular lead (in case one lead fails) may be appropriate for higher risk patients.

In a series of 4694 patients undergoing valve surgery between 1992 and 2002 at the Brigham and Women's Hospital, a multivariate analysis established the following as risk factors for conduction disturbances requiring PPM implantation: RBBB [odds ratio (OR) 3.6], LBBB (OR 2.0) and PR interval more than 200 ms (OR 1.9) on the preoperative ECG, multivalve surgery involving the TV (OR 3.7) or not involving it (OR 2.1), advanced age (OR 1.4), and a history of prior valve surgery (OR 1.8).[18] For surgery involving only one valve, the risk was lowest for mitral valve surgery (3.5 percent), somewhat higher for aortic valve surgery (5.1 percent), and highest for TV surgery (12 percent). On the basis of the preoperative ECG, the need for permanent pacing was greatest in those with a preexisting isolated RBBB (18 percent) or an RBBB accompanied by a left hemiblock (bifascicular block; 16 percent) and somewhat lower in those with a preexisting LBBB (10 percent). A prediction rule for the need for permanent pacing was developed according to the point system shown in Table 44-1. The need for permanent pacing for total point scores of 0, 1, 2, 3, 4, 5, and 6 was 1.9, 5.2, 8.7, 12, 21, 36, and 50 percent, respectively.[18] In a recent retrospective review of 4999 patients undergoing cardiac surgery between 1993 and 2005, the strongest predictors of pacemaker implantation were LBBB and aortic valve surgery. TV repair was not associated with an increased rate of pacemaker implantation, though these patients made up a minority of the cases (7 percent).[19] Similar to coronary bypass surgery, repeat valve replacement operations are associated with increased risk of long-term conduction disturbance, requiring a PPM in as many as 16 percent of patients.[10] A better understanding of what constitutes a high-risk patient will help providers avoid delays in PPM implantation and facilitate patient mobilization and discharge.

## Prophylaxis for Postoperative Atrial Fibrillation

Postoperative atrial fibrillation occurs in 10 to 40 percent of all patients undergoing open heart surgery.[20–23] The issue of

**TABLE 44-1: Risk Score to Predict Permanent Pacing After Valve Surgery**

| Variable | Points |
|---|---|
| Preoperative electrocardiogram | 2 |
| Right bundle branch block | 1 |
| Left bundle branch block | 1 |
| PR interval >200 ms | |
| Multivalve surgery | 2 |
| Tricuspid valve included | 1 |
| Tricuspid valve not included | |
| Other | 1 |
| Age 70 years or above | 1 |
| Prior valve surgery | |

prophylactic pacing after cardiac surgery as prophylaxis for atrial fibrillation was addressed in a meta-analysis of eight trials that enrolled a total of 776 patients and compared control patients with patients randomized to right atrial, left atrial, or biatrial pacing.[24] The patients could be paced at a fixed high rate (fixed high-rate pacing) or at a rate just fast enough to overcome the intrinsic rate (overdrive pacing). Risk reductions for postoperative atrial fibrillation of 2.6-fold and 1.8-fold were found for overdrive biatrial and right atrial pacing, respectively, and there was a 2.5-fold reduction for fixed high-rate biatrial pacing. Whether biatrial pacing confers an advantage over right atrial pacing is controversial.[25,26] Ongoing studies should help clarify these issues. Although temporary atrial pacing to decrease atrial fibrillation after cardiac surgery has gained general acceptance, the data supporting permanent pacing are not well established.

Although medical therapy with prophylactic β-blockers, amiodarone, and sotalol has been shown to reduce postoperative atrial fibrillation, pacing therapy offers several advantages, including minimal expense; no association with ventricular proarrhythmia, bradycardia, or hypotension; and no need for the initiation of therapy before surgery. In summary, the approximately 2.5-fold risk reduction associated with biatrial pacing (either overdrive or fixed high rate) and overdrive right atrial pacing makes pacing an attractive nonpharmacologic method for preventing atrial fibrillation after cardiac surgery, particularly since atrial epicardial wires are in place.

## Pacing in Cardiac Transplantation

Bradycardia after cardiac transplantation is common, usually temporary, and often due to SND. Although the most common cause for this SND is probably surgical trauma at the time of transplantation,[27] several other causes have been implicated, including disruption of the blood supply to the sinus node,[28] ischemic time,[29] rejection,[30] donor age,[31] and pretransplant amiodarone use.[32]

Until the early 1990s, the standard anastomosis between the recipient and donor hearts was a biatrial anastomosis, as originally described by Lower and Shumway in the canine heart in 1960.[33] As the biatrial anastomosis requires opening the recipient right atrium from the inferior vena caval (IVC) orifice with transection and oversewing of the recipient superior vena cava (SVC), the suture line may result in direct damage to the donor sinus node as well as the blood supply to the sinus node.[34] In the bicaval anastomosis, which came into widespread use in the 1990s, there are direct donor–recipient anastomoses of the IVC and SVC, although the left-sided anastomosis may occur at the level of the pulmonary vein or left atrium, depending on the technique used.[35,36] As might be expected, several studies have documented a decreased need for pacing with the use of the bicaval anastomosis compared with the standard biatrial anastomosis.[34,37–39] In the two randomized studies that compared the need for permanent pacing on the basis of the type of anastomosis used, permanent pacing was required in 5 (6.5 percent) of 75 patients with the biatrial anastomosis but was not required in any of the 81 patients with the bicaval anastomosis. According to a compilation of six studies, permanent pacing was required in 60 (9.2 percent) of 651 patients with biatrial anastomoses compared with only 1 (0.3 percent) of 340 patients with bicaval anastomoses. Although the incidence of prolonged SND has been reduced with bicaval anastamoses, this benefit may be attenuated in the era of extended donor criteria. Posttransplant PPM requirements were examined in 88 patients who underwent a bicaval anastamotic approach between 2000 and 2004. Ultimately, 18 of the 88 (20.5 percent) required PPM implantation. Mean donor age was the major risk factor for postoperative pacemaker requirement (44.7 years vs 35.7, $p = 0.0289$) and may suggest a predilection for increased susceptibility to perioperative ischemia and a higher incidence of underlying conduction and coronary disease in older hearts.[40]

The initial approach to a cardiac transplant patient with postoperative bradycardia resulting from SND is medical therapy with chronotropic agents and the use of operatively placed temporary epicardial leads if necessary. Theophylline has been shown to improve prolonged chronotropic dysfunction in transplant recipients and is the drug of choice.[41] Isoproterenol and terbutaline also may be used. Published commentaries generally have recommended permanent pacing if bradycardia caused by SND persists for 2 to 3 weeks.[34,42] Ambulatory Holter monitoring may aid in the decision whether to implant a PPM. The reason to wait as long as possible to implant a permanent system is that SND after transplantation is usually manifest by the first week and resolves over 1 to 3 months. Serial electrophysiologic studies in 40 posttransplant patients demonstrated that the sinus node recovery time (SNRT) became abnormal by the first week in 6 (15 percent) patients and by 3 months in 1 other patient. In all six patients with early SND, the SNRT returned to normal

by 6 weeks, although sinoatrial conduction abnormalities persisted in two patients.[43] Because maintaining AV synchrony will maximize cardiac output, a dual-chamber pacemaker system usually is used and programmed to DDDR, although permanent atrial pacing without a ventricular lead is an option (albeit one rarely used in the United States) if AV conduction is intact. One advantage of using an atrial lead only is the decreased likelihood of dislodgment with biopsy, although this is uncommon with experienced operators. If a biatrial anastomosis is present, the pacemaker lead should be implanted in the anteroseptal right atrium rather than the lateral right atrium near the anastomosis.

## Cardiac Resynchronization Therapy (Biventricular Pacing)

Heart failure is the fastest growing cardiovascular diagnosis in the United States with an estimated prevalence of 2.5 percent in adults and an estimated cost of over $39.2 billion in 2010.[44] Heart failure syndromes represent a constellation of molecular, anatomic, and neurohormonal perturbations. One downstream effect of neurohormonal regulation includes the alteration of myocardial membrane properties leading to action potential prolongation, an imbalance of calcium homeostasis, and cell–cell coupling. These changes ultimately lead to interventricular dyssynchrony (often LBBB) and greater arrhythmogenicity. Although great strides have been made using medications to target and attenuate the negative remodeling process that ensues with heart failure, biventricular pacing to restore cardiac synchrony provides another arrow in the quiver to combat heart failure morbidity and mortality.

CRT has proven beneficial for patients with dilated cardiomyopathy, intraventricular conduction delay, and heart failure. The objective is to correct dyssynchrony by pacing the left ventricle alone or both ventricles (biventricular).

The Multisite Stimulation in Cardiomyopathy (MUSTIC) study showed statistically significant improvements in the 6-min walk and quality of life (but not mortality) with biventricular pacing,[45] and the Multisite InSync Randomized Clinical Evaluation (MIRACLE) study has shown improvements in functional class, quality of life, and left ventricular (LV) dimensions.[46] Resynchronization therapy in the COMPANION (Comparison of Medical Therapy, Pacing, and Defibrillation in Heart Failure) trial directly compared pacing with (CRT-D) and without (CRT-P) defibrillation capability with optimal medical therapy.[47] CRT-D reduced mortality by 36 percent compared with medical therapy, but there was insufficient evidence to conclude that CRT-P was inferior to CRT-D. The effects of CRT on mortality were further evaluated in the CARE-HF trial. Enrollment criteria included New York Heart Association (NYHA) class III/IV heart failure, LVEF <35 percent, QRS ≥120 ms. In both trials the risk of death was reduced with CRT versus no pacing; however, only CARE-HF demonstrated statistical significance (HR 0.64, $p$ <0.002).[47,48] No large trial has yet demonstrated clinical benefit among patients without QRS prolongation, even when they have been selected for echocardiographic measures of dyssynchrony.[49]

The benefit for implantable cardioverter-defibrillator (ICD) implantation in heart-failure patients has been well established based on SCDHeFT and MADIT-II data showing a survival benefit with defibrillators in patients with class II or III heart failure and a severely depressed ejection fraction.[50–52] More recently, the MADIT-CRT trial compared the use of a CRT plus an ICD device versus an ICD alone in 1820 patients with NYHA class I or II heart failure, LVEF ≤30 percent, and QRS ≥130 ms. This study included both ischemic and nonischemic cardiomyopathy patients and demonstrated a reduction in the primary combined endpoint of death or heart failure events in the CRT-D group (17.2 vs 25.3 percent, $p$ = 0.001). This was driven primarily by a 41 percent reduction in heart failure events.[53]

Based on these data, current guidelines recommend CRT with biventricular pacing in patients with NYHA class III or ambulatory class IV heart failure, LVEF of 35 percent or less, and a QRS duration greater than 120 ms,[4] or NYHA class I or II with LVEF ≤30 percent and QRS ≥130 ms.

Since the left ventricle is usually paced via the coronary sinus, transvenous LV pacing is more technically difficult than is endocardial right ventricular pacing. A number of challenges exist with coronary sinus lead placement including difficulty accessing the coronary sinus ostium, unfavorable venous anatomy, and poor pacing parameters owing to myocardial fibrosis, or extracardiac stimulation. Transvenous coronary sinus leads can ultimately be placed successfully about 90 percent of the time. For the remaining cases, an alternative approach may be used such as surgical epicardial placement or transseptal or transapical LV endocardial placement, as discussed below.

## Hypertrophic Obstructive Cardiomyopathy

The objective of permanent pacing in patients with hypertrophic obstructive cardiomyopathy is to improve outflow obstruction with early stimulation of the right ventricular apex. The pacemaker is generally programmed to DDD mode with leads in the right atrium and RV. Randomized clinical studies[54–56] have shown statistically significant reductions in the LV outflow tract pressure gradient but only mild improvement in functional status and generally no improvement in quality of life. There are currently no data available to suggest that pacing changes the natural history of hypertrophic cardiomyopathy (HCM). Therefore, routine implantation of dual-chamber pacemakers should not be advocated in all patients with symptomatic obstructive HCM. Patients who may benefit the most are those with significant gradients (more than 30 mm Hg at rest or more than 50 mm Hg provoked). Myomectomy and ethanol septal ablation are probably more effective treatment options for patients with hypertrophic obstructive cardiomyopathy. Complete heart block can develop after transcoronary alcohol ablation

of septal hypertrophy in patients with HCM and should be treated with permanent pacing. The decision whether to implant a pacemaker alone or a pacemaker–defibrillator is based on clinical judgment but may be guided by several factors that, if present, favor a pacemaker–defibrillator. These factors are a personal history of syncope or sudden cardiac death, a family history of sudden cardiac death, nonsustained ventricular tachycardia (VT), massive hypertrophy (wall thickness of 30 mm or more), a pathologic drop in blood pressure with exercise, and HCM mutations associated with an increased risk for sudden cardiac death.

### Pacing After a Myocardial Infarction

In patients who have had a myocardial infarction, temporary pacing is a class I indication for the following conditions[4]:

1. Asystole
2. Symptomatic bradycardia
3. Bilateral BBB [alternating BBB or RBBB with alternating left anterior/posterior fascicular block (LAFB/LPFB)]
4. Asymptomatic Mobitz 2 AVB
5. New bifascicular block (LBBB or RBBB with left hemiblock)

Permanent pacing is a class I indication for the following conditions[4]:

1. Persistent second-degree AVB in the His–Purkinje system with alternating bundle branch block or third-degree AVB within or below the His–Purkinje system after ST-segment elevation MI. (Level of Evidence: B)
2. Transient advanced second- or third-degree infranodal AVB and associated bundle branch block. If the site of block is uncertain, an electrophysiological study may be necessary. (Level of Evidence: B)
3. Persistent and symptomatic second- or third-degree AVB. (Level of Evidence: C)

Permanent pacing usually is not indicated after a myocardial infarction for transient second- or third-degree AVB in the absence of a wide QRS (e.g., with an isolated LAFB). The long-term prognosis for survivors of myocardial infarction who have had AVB is related primarily to the extent of myocardial injury and the character of intraventricular conduction disturbances rather than the AVB itself.

## PACEMAKER LEADS AND TECHNIQUES FOR IMPLANTATION

### Temporary Endocardial Leads

Temporary endocardial leads usually are introduced via a sheath system in a jugular or subclavian vein. The right internal jugular vein is generally the vein of choice, as it allows for easy passage of the pacing lead through the right atrium and into the RV. As these leads usually are placed in the intensive care unit, often without the aid of fluoroscopy, the position of the lead initially is gaged by viewing the intracardiac electrogram (the distal end of the pacing lead is attached to a cardiac monitoring system). As the lead traverses the right atrium and tricuspid annulus, a large amplitude P wave will transition to a large R wave. Premature ventricular beats and injury current indicate that the lead is in contact with the right ventricular myocardium. A common pitfall is pacing the tricuspid annulus. Because this is an unstable position, the lead should be advanced amply into the RV. After the introduction of the lead and verification of appropriate pacing thresholds, the lead should be locked into place in the sheath and its position should be verified with chest radiography.

### Permanent Endocardial Leads

Endocardial leads may be fixated actively or passively. The technique for the introduction of permanent endocardial leads is discussed in detail below. In active fixation, a screw mechanism attaches the lead to the endocardium. Passive fixation leads have polyurethane or silicon tines that facilitate attachment to trabeculae. Passive atrial pacemaker leads are designed for placement in the trabeculations of the right atrial appendage. Passive ventricular leads are designed for placement in the apex of the RV with its trabeculations. Placement of leads in other areas of the atrium and ventricle generally requires active fixation for stabilization. Pacing thresholds may be slightly higher with active fixation, although this is rarely of any consequence. Pacing thresholds may increase after active fixation as a result of inflammation and fibrosis at the site of injury. Most leads are now laden with steroids to minimize the inflammatory response. Active fixation leads are more likely to perforate, particularly at the RV apex, but passive leads may have higher rates of acute dislodgement, particularly in the atrium. Active fixation leads are thought to be easier to extract, though little data exists to support this. In general, the two leads have similar sensing characteristics.

### Technique for Implantation of Permanent Endocardial Leads

The subclavian approach is currently the standard approach for the placement of endocardial leads and is used for the placement of over 75 percent of those leads.[1] This approach has evolved since Furman and Schwedel[57] reported successful transvenous endocardial pacing via the brachial vein in 1959. Because of a high rate of lead dislodgement, this approach was replaced briefly by the external jugular vein approach.[58] The cephalic cut-down approach became the standard in the late 1960s[59] and remained the standard for over a decade. As a result of the introduction of the peel-away sheath for the percutaneous introduction of leads, the subclavian approach emerged and remains the standard.[60] In a series of 200 consecutive patients randomized to endocardial lead insertion via a subclavian approach or a cephalic approach, successful lead placement was achieved in 99 percent randomized

to the subclavian approach and 64 percent of cases with the cephalic approach.[61] The total procedure time was 86 ± 22 min with the subclavian approach and 98 ± 35 min with the cephalic approach ($p$ <0.01). Blood loss was also less with the subclavian approach (55 ± 13 mL vs 115 ± 107 mL; $p$ <0.01).

The following approach is adapted from Calkins and coworkers and is used at the authors' institution[61]:

1. The patient is positioned supine on the fluoroscopy table and a venogram is performed to guide vascular access. Approximately 10 mL of 1:1 contrast dye and normal saline solution is injected via an intravenous (IV) line placed distally in an ipsilateral vein and then flushed with 25 to 50 mL of saline.
2. A sterile field is created.
3. Generous local anesthesia is given (this may be sufficient, but light sedation often is needed).
4. A subcutaneous generator pocket is created by an incision 2 cm below and parallel to the clavicle. The pocket is created along the pectoralis fascia (Fig. 44-2).
5. Once the axillary and subclavian veins have been opacified, a 5F-micropuncture needle attached to extension tubing and a 10-mL syringe is positioned at a 60° angle to the plane of the skin and parallel to the axillary vein (Figs. 44-3 and 44-4). Adjustment of the site of needle entry may be necessary to ensure that the needle enters the vein as it crosses over the first rib.
6. A micropuncture guidewire is advanced through the needle to the SVC and is replaced by a 5F-micropuncture sheath that allows the introduction of a 50-cm, 0.035-in J-tipped guidewire.
7. A peel-away sheath (generally 7–9F) is advanced over the 0.035-in guidewire.
8. The ventricular lead is advanced through this sheath, and the sheath then is peeled and removed. The ventricular lead is advanced into the right ventricular apex under fluoroscopy.

Prospective randomized comparison of the safety and effectiveness of placement of endocardial pacemaker and defibrillator leads using the extrathoracic subclavian vein guided by contrast venography versus the cephalic approach. *Pacing Clin Electrophysiol* 2001;24:456–464. Copyright © John Wiley & Sons.)

9. If an atrial lead is planned as well, a second subclavian venipuncture is made, and the atrial lead is placed with the use of the same technique.
10. The leads are connected to the generator, and then pacing and sensing measurements are obtained.
11. If measurements are satisfactory, the lead is screwed in (active fixation) or securely placed among trabeculae (passive fixation). The leads are secured by suture sleeves within the device pocket.
12. The pocket is irrigated with antibiotic solution.
13. The excess lead is coiled and placed into pocket along with the generator.[61]

Copyright © John Wiley & Sons.)

In general, if the leads are placed too far laterally, there is a greater risk of arterial puncture, whereas if the placement is too medial, there is increased risk of entrapment by the costoclavicular ligament and/or the subclavius muscle.[62]

If the cephalic approach is used, an oblique incision is made just lateral to the deltopectoral groove at the level of the coracoid process of the scapula. A pocket is created, using standard techniques. After dissection down to the pectoralis fascia and identification of the fat pad, the cephalic vein is dissected free, with proximal and distal control of the vein obtained by using permanent silk sutures. A small venotomy is made in the cephalic vein, which is held open with a vein pick. A standard 50-cm 0.035-in J-tipped guidewire is introduced, and one or two endocardial leads are placed, using standard peel-away sheaths.[61]

## Antibiotic Prophylaxis for Endocardial Leads

Several randomized clinical trials have demonstrated reduced infectious complications following permanent device implantation with empiric periprocedural antibiotic administration.[63] A recent trial by De Oliveiri et al. randomized patients undergoing device implantation in a 1:1 fashion to preimplant antibiotics (1 g cefazolin) or placebo. The study was stopped early due to a five-fold rate of infection in the placebo arm. Predictors of infection included no antibiotics, hematoma, and longer procedure duration.[64] In our institution, 1 g cefazolin (or 1 g clindamycin for patients with penicillin allergy) is given before the procedure. After the procedure, 1 g cefazolin is given every 8 h for a 24-h period. Due to the paucity of clinical data supporting prolonged oral antibiotic therapy, the authors no longer administer additional antibiotics for prophylaxis. There is general consensus that antibiotics should be stopped once the wound is closed or within 24 h of wound closure.

## Temporary Epicardial Leads

Temporary atrial and ventricular epicardial pacing wires are passed superficially through the epicardial surface, with the atrial wires secured superficially with fine polypropylene sutures. The duration of capture with these wires varies, but most start to fail after a week or two. Once they no longer are needed, they generally are extracted, with traction applied to the leads as they emerge from the thorax; this usually causes the suture to break or the lead to pull out from the epicardial surface. This usually does not result in any bleeding.

## Permanent Epicardial Leads

Permanent epicardial leads either screw into the myocardium or are fixed actively in contact with the epicardial surface with deeper polypropylene sutures. As discussed below, placement of permanent epicardial leads requires a small thoracotomy. Any lead can be placed through such a thoracotomy, using standard open surgical techniques. Despite the small size of the thoracotomy, placement of these leads may result in significant postoperative pain, probably because significant force must be applied to spread the ribs during the procedure. There has been increasing experience with placement of epicardial leads using a robotic arm, particularly when a LV lead has to be placed for a biventricular pacing system, as is discussed below. One advantage of this technique is a significant reduction in postoperative pain as a result of the need for only a few small incisions for the arm, camera, and so on.

## Technique for Standard Surgical Placement of Epicardial Leads

Epicardial leads may be placed with the subxiphoid approach or an anterior thoracotomy approach. The subxiphoid approach is preferred in patients without prior cardiac surgery and is performed as follows:

1. With local anesthesia, a vertical midline incision is made below the xiphoid process.
2. The rectus sheath and anterior diaphragm are exposed.
3. The xiphoid process is retracted superiorly or removed, and the subcutaneous fat is dissected.
4. The diaphragmatic portion of the pericardial surface is exposed and opened.
5. Epicardial screw-in leads are attached to the right ventricular free wall.
6. The pericardium is closed around the leads.
7. The generator is placed in the subcutaneous tissue.

The anterior thoracotomy approach often is reserved for patients with prior cardiac surgery and is performed as follows:

1. Access is via the left fifth intercostal space.
2. The anterolateral left ventricle is exposed.
3. The leads are fixed and then tunneled subcutaneously to the pulse generator, which usually is placed in the left upper quadrant of the abdomen.

## Robotic Arm Placement of the Left Ventricular Lead for Biventricular Pacing Systems

In approximately 10 percent of patients referred for a biventricular pacing system, placement of the coronary sinus lead is unsuccessful. In these situations, a surgical LV epicardial lead may be considered. There has been increasing experience with minimally invasive LV epicardial lead placement, using a robotic surgical system such as the da Vinci Robotic Surgical System (Intuitive Surgical, Sunnyvale, CA). In a series of 10 patients[65] in which 19 epicardial leads were placed

(1 patient received only 1 lead), mean robotic operative time for all cases was 83 ± 53 min (range 30–80 min) and was significantly lower in the last five cases (50 ± 16 min) compared with the first five cases (108 ± 54 min). All the patients were alive and well 25 ± 10 weeks after follow-up with significant improvement in NYHA class and LVEF observed. Reported complications included one inadvertent injury to the LV free wall (corrected with robotically placed pledgeted sutures) early in the series. This was attributed to mediastinal shift associated with mechanical ventilation that allowed the LV to move toward the chest well; in subsequent cases, mechanical ventilation was held during lead placement. One patient developed left lower lobe pneumonia 3 days after the procedure. No blood transfusions or reoperations for bleeding were required.

According to the authors, their surgical approach is as follows. The patient is placed in a right lateral decubitus position. In the seventh intercostal space at the posterior axillary line, a camera port is placed. The left and right instrument arms of the robot are passed through ports placed in the ninth and fifth intercostal spaces, respectively. The left chest is insufflated with $CO_2$ to a pressure of 8 to 10 mm Hg, and a 10-mm working port (for the introduction of the lead and sutures) is inserted posterior to the camera port. The pericardium is opened and retracted posterior to the left phrenic nerve. The first and second obtuse marginal (OM) vessels are identified. The pacing lead is introduced through the working port and then secured in place with the robotic arms. (More commonly, a screw-in lead is used, but epicardial steroid-eluting sew-on leads were used in two patients.) In most cases, the lead was placed between the second and third OM vessels, which corresponded to the time of latest ventricular activation as measured by a temporary pacing lead. The pericardium is closed over the permanent leads, which are tunneled to a counterincision in the axilla. After chest tube placement for evacuation of air, the port sites are closed and the patient is repositioned to a supine position and redraped. The leads are then connected to a preexisting device in the pocket or to a new device.[65]

## Left Ventricular Endocardial Pacing

LV pacing via the coronary sinus may be unsuccessful because of anatomical variation, phrenic nerve stimulation, or lead instability. Furthermore, it is estimated that as many as 20 to 30 percent of patients with stable lead placement will have no significant benefit from CRT (nonresponders).[66,67] For these patients alternative methods of pacing the LV endocardium may offer some hope. Several patient series have described techniques for accessing the left ventricle by either a transseptal or a transapical approach.[68–71] In addition to being technically challenging, most agree that an indwelling LV pacing lead poses a stroke risk and requires long-term anticoagulation. Although these techniques are still under development, they remain promising as alternatives for patients with difficult coronary sinus lead placements and/or poor response due to lead location.

# PROGRAMMING PACEMAKERS

## Nomenclature

Pacing modes usually are described with codes consisting of three or four letters. The first letter refers to the chambers paced: A for atrium, V for ventricle, D for both, and O for neither (pacing is turned off). The second letter refers to the chambers sensed, using the same abbreviations employed for pacing (O denotes that sensing is turned off and asynchronous pacing will occur). The third letter refers to the action taken by the pacemaker in response to a sensed signal and may be one of the following: I (inhibit), T (trigger), or D (dual response of inhibiting or triggering for dual-chamber devices). If a fourth letter is used, it is usually R, which refers to rate-responsive pacing. Rate-responsive devices contain a sensor that can adjust the rate in response to temperature, minute ventilation, oxygen saturation, vibration, and other variables. This facilitates appropriate adjustment in heart rate that is based on an individual's physical activity. Dual-chamber pacing often is referred to as physiologic pacing.

## DDD Mode

In the DDD(R) mode, the pacemaker paces and senses both chambers, with the ability to inhibit or trigger a cardiac depolarization in response to a sensed signal. For example, if an intrinsic atrial beat is sensed within a time interval that corresponds to a programmed heart rate threshold (typically 60 bpm), the pacer will not trigger an artificial atrial beat (atrial pacing is inhibited). If the intrinsic atrial rate is slower than the programmed rate, the atrial lead will trigger an artificial atrial depolarization. As the atrial beat travels through the AV conduction system, the ventricular lead will sense whether the impulse has propagated into the ventricle within a preprogrammed time interval (e.g., 200 ms). If the ventricular lead senses intrinsic depolarization, it will not trigger an artificial ventricular beat (i.e., ventricular pacing is inhibited). If after the set time interval the ventricular lead does not sense intrinsic depolarization, it will trigger an artificial ventricular beat. This mode is especially useful for patients with AVB, a need for AV synchrony to maximize cardiac output, or a history of pacemaker syndrome (see "Pacemaker Complications" section below).

## DDI Mode

In the DDI(R) mode, the pacemaker is programmed to pace and sense both the atrium and the ventricle. In response to a sensed signal, the pacemaker will inhibit the output of an artificial depolarization. For example, if the intrinsic atrial rate is slower than the programmed rate, the atrial lead will trigger an artificial atrial depolarization. Unlike the DDD mode, DDI will not trigger a ventricular artificial depolarization on the basis of atrial activity. The only scenario in

which the ventricular lead will trigger an artificial depolarization occurs when the intrinsic ventricular rate is below a programmed threshold.

## VVI Mode

In the VVI(R) mode, the pacemaker paces and senses only the ventricle. If an intrinsic ventricular signal is detected, the ventricular lead will not trigger an artificial ventricular depolarization. This mode is particularly useful for patients with persistent atrial arrhythmias such as atrial fibrillation. Unlike the DDI(R) mode, the VVI(R) mode does not pace the atrium if an intrinsic atrial signal is absent. The disadvantage of this mode compared with DDI(R) is AV dyssynchrony with possible compromise of cardiac output as a result of impaired diastolic filling of the left ventricle if there is a native organized atrial rhythm.

## Mode Switching

Mode switching refers to switching to a mode that is not capable of tracking atrial beats. This is useful in patients with intermittent atrial tachyarrhythmias. Examples are switching from DDDR to DDIR and from DDD to VVI. Although patients with AV nodal ablation for atrial fibrillation may receive greater symptomatic benefit with DDDR and mode switching compared with VVIR,[72] the MOST trial suggested that among patients with SND and paroxysmal atrial fibrillation, DDDR and mode switching do not have any symptomatic benefit.[73]

## Other Modes

In the AAI(R) mode, the pacemaker paces and senses only the atrium. If an intrinsic atrial signal is sensed, the pacemaker will not trigger an atrial depolarization. This mode may be appropriate for patients with SND and intact AV conduction. The disadvantage of this mode is the lack of ventricular pacing if AVB occurs. In a selected group of patients who were screened to find out if they had intact AVN function, the occurrence of clinically significant AV nodal disease was less than 2 percent/year. This mode is used rarely in the United States.

In the DOO mode, both chambers are paced but not sensed. This mode may be used as a temporary mode during surgery to prevent an interaction between the electrocautery and pacemaker sensing. Such an interaction could result in bradycardia or asystole as a result of inappropriate inhibition of ventricular pacing or rapid ventricular pacing resulting from inappropriate electrocautery sensing by the atrial lead with triggered pacing of the ventricle. In the VOO mode, the ventricle is paced but not sensed. The indication is the same as for DOO. Pacemaker-dependent patients who are undergoing cardiac surgery should be switched to one of these modes before surgery.

## Perioperative Device Programming

Both inpatient and outpatient surgical procedures present challenges to health care providers when patients have implantable cardiac rhythm management devices (pacemakers and defibrillators). Most of the concerns center around potential interaction between the device and an electromagnetic field which can cause inability of the device to deliver pacing or shocks, lead–tissue interface damage, changes in pacing behavior, electrical reset to the backup pacing mode, or inappropriate ICD therapies. Electromagnetic interference (EMI) has been reported with MRI scanners, electrosurgery, TENS units, lithotripsy, electroconvulsive therapy, radiation therapy, and radiofrequency ablation among others. Previous guidelines have recommended that all patients with implantable devices have the device interrogated before and after surgery in order to assure proper device function during the perioperative period. In truth, patients with pacemakers who are not pacemaker dependant need no reprogramming. Similarly, pacemaker-dependant patients undergoing procedures involving the groin, lower extremities, or upper extremities distal to the elbow need no reprogramming of the device.[74] At the author's institution, patients undergoing surgery in the head, neck, chest, abdomen, or upper extremities proximal to the elbow are reprogrammed to asynchronous pacing if pacemaker-dependent, and ICD tachycardia therapies are disabled on the day of surgery. Temporary pacing and defibrillation equipment should be readily available. After the operation, the original device settings should be restored with interrogation of the lead parameters. This is particularly important for patients undergoing cardiac surgery during which device leads may become disrupted or dislodged.

# PACEMAKER COMPLICATIONS

## Complications Related to Implantation

Pacemaker complications can be divided into complications associated with implantation, pacemaker infections, subsequent loss of capture, pacemaker syndrome, and pacemaker-mediated tachycardia.

Implantation complications may be related to venous access, the endocardial lead, or the pocket. Complications related to venous access are (1) pneumothorax and hemothorax, (2) incidental arterial puncture, and (3) brachial plexus injury. The incidence of pneumothorax or hemothorax with the subclavian endocardial approach has been estimated to be 1 to 3 percent.[75,76] Complications associated with the endocardial lead are (1) atrial or ventricular perforation, tamponade, and complete heart block, (2) chest wall or diaphragmatic stimulation, and (3) venous thrombosis or endocarditis. Complications associated with the pocket are (1) hematoma (appropriate electrocautery use helps avoid this complication), (2) infection, (3) skin compromise, and (4) generator migration. A complete discussion of pacemaker lead and generator infections follows.

## Pacemaker Lead Infections

Patients may present with systemic infection and pacemaker lead endocarditis or local infection. According to a series involving 52 patients, patients with pacemaker lead endocarditis may present early after pacemaker implantation or late with chronically infected leads. In this series, there was fever in 87 percent, pulmonary involvement in 38 percent, positive blood cultures in 88 percent (most frequently *Staphylococcus* in 94 percent of positive cultures), and abnormalities on the lead by transesophageal echocardiography in 94 percent, often not seen with transthoracic echocardiography.[77]

In patients with local infection, conservative therapy may be considered for very low grade infections or minor skin erosions. In patients who present with a pocket abscess or significant skin erosions, conservative treatment (antibiotics, limited debridement, and irrigation) probably will result in failure.[78,79] Generator removal only and/or partial lead extraction are also likely to result in persistent infection.[78–80]

The decision whether to perform percutaneous or surgical lead extraction for vegetations larger than 1 to 2 cm is controversial. In the series mentioned above, the 10 patients with vegetations larger than 10 mm were referred for surgical lead removal, and 2 of them died of septic complications.[77] Although the authors documented a significant rate of septic pulmonary embolism of 30 percent in the entire cohort,[77] most of those cases were without significant clinical sequelae, and so there is still no strong evidence that surgical extraction is preferable to percutaneous extraction for large vegetations.

## Loss of Capture

Loss of capture may be due to (1) lead dislodgment, (2) lead fracture, (3) a break in lead insulation, and (4) fibrosis at the lead–myocardial interface (increased pacing threshold). Pacemaker interrogation and echocardiography are useful in determining the cause of the loss of capture. For example, lead fracture is associated with high impedance, whereas loss of lead insulation is associated with low impedance.

## Other Complications

Pacemaker syndrome is caused by the absence of AV synchrony during ventricular pacing, usually resulting in atrial contraction against closed AV valves. Since the atrial contraction may result from retrograde conduction of a ventricular pacing impulse, this syndrome may be more common in patients with SND and intact AV conduction than it is in those with AVB. Symptoms of pacemaker syndrome include light-headedness, weakness, flushing, exercise intolerance, and palpitations. The syndrome may be treated by restoration of AV synchrony with DDD pacing.

In pacemaker-mediated tachycardia, the ventricular impulse is conducted retrograde through the AVN to the atria, where it is sensed by the atrial lead in a dual-lead system, with the resulting ventricular-paced beat triggered by the atrial-sensed beat. The acute remedy is to place a magnet over the pacemaker. The long-term remedy is to reprogram the pacemaker to increase the postventricular atrial refractory period (PVARP) or change the mode from DDD to DDI.

# EXTRACTION OF PACING AND DEFIBRILLATING LEADS

## Indications

After the initial implantation of a pacing lead, some degree of thrombosis develops and, on areas that are in contact with the endothelium or endocardium, organizes into fibrosis that may propagate along the lead and over time become increasingly dense and calcified (calcification is more common in very old leads). This fibrotic tissue makes lead removal difficult, necessitating extraction with more sophisticated tools. The most common sites for fibrosis are the venous entry site, the curve into the SVC, and the region from the anode ring to the lead tip.[81]

Experts in complex lead management make the distinction between explanting a lead (simple traction) and lead extraction (use of specialized tools for lead removal).[82] The most common indication for lead extraction is infection, sometimes involving only the pocket but often resulting in vegetations on the pacemaker leads. The most recent class I and class II indications for extraction of chronically implanted leads are listed in Table 44-2.

## Procedural Strategies

Early strategies for lead removal made use of simple traction (later modified to prolong the period of traction with a weight and pulley system) or open chest surgery with cardiopulmonary bypass. As earlier generations of leads were thicker and had greater resistance to loss of integrity during simple traction, this method was often successful. Excessive force, however, created the risk of avulsion of myocardium with resulting tamponade. Experience with surgical extraction of pacemaker leads has been described.[83,84] Generally, surgery is reserved for patients who fail percutaneous extraction and those with large pacemaker lead vegetations, as discussed below.[77]

The need for a safer, faster, and more consistent technique was satisfied by the development of the counter-traction technique that was developed in the late 1980s and evolved during the 1990s.[85,86] This technique employs stylets that are attached to the lead to apply traction while the operator uses a sheath surrounding the lead to free the lead from the fibrotic myocardium and apply countertraction, as shown in Table 44-2.

**TABLE 44-2: Indications for Extraction of Chronically Implanted Transvenous Pacing and Defibrillator Leads[a]**

Class I indications: Complete device and lead removal in patients with:

- Definite CIED system infection, as evidenced by valvular endocarditis, lead endocarditis or sepsis (Level of evidence: B)
- CIED pocket infection as evidenced by pocket abscess, device erosion, skin adherence, or chronic draining sinus without clinically evident involvement of the transvenous portion of the lead system (Level of evidence: B)
- Valvular endocarditis without definite involvement of the lead(s) and/or device (Level of evidence: B)
- Occult gram-positive bacteremia (not contaminant) (Level of evidence: B)
- Life-threatening arrhythmias secondary to a retained lead fragment
- A retained lead, a lead fragment, or extraction hardware that poses an immediate or imminent physical threat to the patient
- Clinically significant thromboembolic events caused by a retained lead or a lead fragment
- Obliteration or occlusion of all usable veins, with the need to implant a new transvenous pacing system
- A lead that interferes with the operation of another implanted device (e.g., pacemaker or defibrillator) or with treatment of malignancy

Class II indications

- Persistent occult Gram-negative bacteremia
- Severe chronic pain, at the device or lead insertion site, that causes significant discomfort for the patient, is not manageable by medical or surgical techniques and for which there is no acceptable alternative
- Ipsilateral venous occlusion preventing access to the venous circulation for required placement of an additional lead, when there is no contraindication for using the contralateral side
- A lead that because of its design or failure may pose a threat to the patient, though the threat is not immediate or imminent if the lead is left in place
- An abandoned functional lead that poses a risk of interference with the operation of the active CIED system
- Leads that are functional but not being used (i.e., RV pacing lead after upgrade to ICD)
- Patients who require specific imaging techniques (e.g., MRI) that cannot be imaged due to the presence of the CIED system for which there is no other available imaging alternative for the diagnosis
- In patients if a CIED implantation would require more than four leads on one side or more than five leads through the SVC

CIED, cardiovascular implantable electronic devices.

[a]Class I indications are those for which there is general agreement that leads should be removed. Class II indications are those for which leads often are removed but there is some divergence of opinion with respect to the benefit versus risk of removal.

Reproduced with permission from Wilkoff B, Love C, Byrd C, et al. Transvenous lead extraction: Heart Rhythm Society expert consensus on facilities, training, indications, and patient management: This document was endorsed by the American Heart Association (AHA). *Heart Rhythm* 2009;6(7):1085–1104.

The extraction procedure is as follows. The generator is removed from the pocket, and the fibrous tissue is separated from the leads down to the subclavian vein, using electrocautery and/or sharp dissection. If a brief trial of gentle traction fails, the countertraction tools are employed. A special locking stylet is chosen according to the size of the lead and advanced as far as possible along the lead and then fixed to the inner coil. A suture is placed tightly around the lead in an attempt to maintain the integrity of the lead during the extraction process. Several sheath options can be employed at this point including mechanical, telescoping, laser, electrosurgical (RF), and a rotating threaded tip sheath. Although traction is applied to the lead, the sheath is advanced along the lead to lyse fibrous attachments. The sheath is generally advanced to within 1 to 2 cm of the electrode tip. As shown in Fig. 44-5, the lead and myocardium are pulled up to the sheath for countertraction, and then continued traction results in release of the lead tip.

Regardless of the tools employed, careful patient selection according to guidelines and procedural preparation are critical to good outcomes. In addition to the primary operator and a scrubbed assistant, an in-house cardiac surgeon should be identified as well as anesthesia backup if the case is not being done under general anesthesia. At the author's institution, all leads older than 6 months are removed in a hybrid operating room with fluoroscopy under general anesthesia. A transesophageal echo probe is passed and remains in place for the duration of the case for real-time monitoring of intracardiac structures and the pericardial space. The radial artery is cannulated for hemodynamic monitoring and venous sheath is placed in the femoral vein for quick conversion to a femoral work station should that become necessary. At a minimum, it is recommended that primary operators will have extracted 40 leads under the supervision of someone who has extracted at least 75 leads. An additional 20 leads/year should be extracted to maintain proficiency.[82]

The overall complete extraction success rate for conventional countertraction in prior series has been reported to be between 87 and 93 percent, with a major complication rate between 1.4 and 2.5 percent.[87,88] Conversion to a femoral approach sometimes is required because of failure with the subclavian approach. The femoral approach allows the operator to grasp the lead and pull it down from the subclavian implant site and then retrieve it by using countertraction from below with a specially designed sheath. The need for a femoral approach occurs about 5 to 10 percent of the time and increases the overall success rate. More recent data collected with a spectrum of extraction techniques suggest

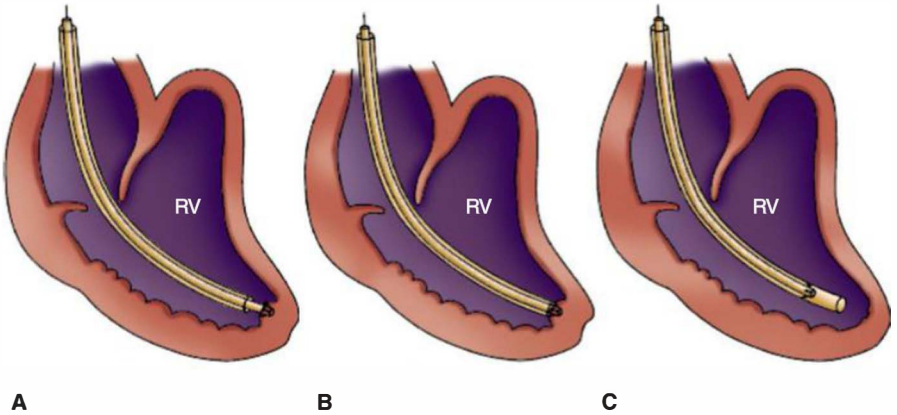

**FIGURE 44-5** Countertraction sequence. **A**. The sheath is advanced to within 2 cm of the lead tip. **B**. The lead and myocardium are pulled up to the sheath to apply countertraction. **C**. The tip releases, and the myocardium falls away. (Reproduced with permission from Love CJ. Current concepts in extraction of transvenous pacing and ICD leads. *Cardiol Clin* 2000;18:193–217. Copyright © Elsevier.)

that major complications remain less than 2 percent in the hands of skilled operators.

The risk of failed extraction increases significantly with increasing age of the lead.[88] Potential major complications of the procedure include death, cardiac tamponade, pneumothorax, hemothorax, pulmonary embolism, arteriovenous fistulas, and stroke.

An excimer laser sheath composed of thin inner and outer polymer walls between which a single layer of optical fibers is embedded is commonly employed for extraction. Proximally, the optical fibers are attached to an excimer laser generator. Distally, pulses of light with wavelengths of 308 nm are delivered to the tissue. Since the penetration of this wavelength of light in vascular tissue is approximately 100 μm, only the fibrous tissue immediately surrounding the sheath tip is destroyed, facilitating lead extraction. The PLEXES (Pacing Lead Extraction with the Excimer Sheath) trial randomized 301 patients with 465 chronic leads to extraction via a subclavian approach with a conventional sheath or the excimer sheath. Complete removal was achieved in 94 percent of the laser group but in only 64 percent of the conventional group. Rather than converting to a femoral approach, leads that failed with the conventional approach were removed with the laser sheath, with a success rate of 88 percent. Significant complications were encountered in less than 2 percent of the patients, but none was attributed directly to the use of the laser.[89] The recent LEXICON study was a multicenter observational trial of 1449 patients undergoing laser-assisted device extraction. Use of the laser was associated with a 97.7 percent clinical success rate and major adverse events in 1.4 percent, including four deaths (0.28 percent), compared with a 2.5 percent major complication rate and an 0.6 percent death rate in a registry involving the conventional approach.[90,91] The Evolution™ mechanical dilator sheath is a useful alternative to the laser sheath with successful extraction reported in over 80 percent of patients.[92] This tool has proven particularly useful in regions of heavy vascular and lead fibrosis or calcification.

## Other Considerations

Nonfunctional leads do not require routine extraction. In most cases, the leads may be abandoned and new leads can be inserted ipsilaterally. A special case is that of Accufix (Telectronics) and Encor™ (Telectronics) atrial leads, which have been implicated as a cause of death in 6 of over 30,000 patients as a result of fracture of the small retention wire used to form the J shape. This family of leads was withdrawn from the market in 1994; however, some 8000 patients still have these leads implanted. Fracture of this retention wire may work its way through the insulation and perforate the heart. Although some physicians initially elected to remove the leads, the incidence of death (about 0.5 percent) from this procedure was found to be higher than that resulting from the lead itself. On the basis of those findings, physicians were advised to manage patients more conservatively by following them with serial fluoroscopy, with consideration of extraction only for certain indications that were based on patient age, duration of implant, and fracture class of the retention wire.[93] In cases of perforation of the insulation by retention wire (class III fracture), it may be possible to snare and selectively retrieve the fractured wire fragment by using percutaneous techniques. Similarly, the Sprint Fidelis is a Medtronic ICD lead implanted in 286,000 patients worldwide. Due to its high rate of failure and predilection for fracture, this lead was voluntarily withdrawn. Failure can involve the pace/sense portion and/or the shocking coils. Pace/sense conductor failures can cause oversensing resulting in inappropriate shocks or pacing failure due to high impendence. Fracture of the high-voltage electrode can cause failure to deliver shocks. Current recommendations include regular device follow-up

and a software patch for longitudinal monitoring. However, a 2008 study showed that impendence monitoring failed to prevent 2/3 of inappropriate shocks.[94]

For occlusion of the subclavian vein, conservative management, including short-term anticoagulation, is often adequate, as these patients generally develop venous collaterals. For patients with SVC syndrome in whom dilatation and stenting is planned, extraction of the lead should be considered.[94,95] The occurrence of pulmonary emboli generally does not mandate lead extraction unless the emboli are clinically significant or recurrent despite appropriate anticoagulation.[93]

Pacing leads implanted inadvertently in the left ventricle should be removed immediately. Chronic LV leads should be treated with anticoagulation, with surgical extraction reserved for recurrent cardioembolic stroke despite anticoagulation. Percutaneous extraction is less desirable because of the potential embolization associated with passing the sheaths over the leads and rarely is performed. In regard to tricuspid regurgitation, lead extraction rarely has been of any benefit and can worsen the condition by damaging the valve.

Defibrillator leads can be extracted with the same percutaneous techniques described for pacing leads, with similar success. Coronary venous leads used for biventricular pacing have been removed with remarkably little difficulty, although there is little experience to date with the Medtronic StarFix™ active fixation coronary sinus lead.

# DEFIBRILLATORS

## General Considerations

ICDs were introduced in the 1980s as a means of rescuing patients from life-threatening ventricular tachyarrhythmias. The detection of VT is based primarily on the ventricular rate rather than the width of the QRS complex on the surface ECG. When the ventricular rate exceeds a programmed threshold, the device delivers a shock to restore the normal rhythm. Current ICD systems may consist of either one or two leads, with the second configuration designed to allow dual-chamber pacing if necessary. The procedure for implanting an ICD system is similar to that for implanting a pacemaker. With the patient under conscious sedation and local anesthesia, a cardiologist or surgeon inserts a pulse generator subcutaneously and inferior to the left clavicle. The pulse generator is connected to the lead(s) in the RV (and the right atrium with two-lead systems). When the ICD fires, the circuit consists of a ventricular coil as one pole and the pulse generator and/or another coil in the SVC/right atrium as the other pole. The pulse generator typically is positioned on the patient's left side, allowing the maximum amount of current to traverse the heart. Of note, ICD leads, like pacemaker leads, may be extracted, but the extraction procedure is more complex because of the ingrowth of tissue into the shock coils. This may be mitigated by the introduction of Gore-Tex-coated coils.

## Modes of ICD Therapy

The ICD classifies a rhythm on the basis of the ventricular rate. For example, most ICDs are programmed to have one to three zones of tachytherapy plus bradycardia pacing. The device delivers the programmed therapy on the basis of the heart rate it detects. Available therapies include bradycardia pacing, antitachycardia pacing (ATP), and shock delivery. In ATP, the device initiates a short burst of rapid ventricular pacing in an effort to interrupt the reentrant tachycardia by creating a critical zone of conduction within the reentrant circuit that is refractory to additional ventricular activation. The shock may be delivered in the form of low-energy cardioversion or defibrillation. Most ICDs are capable of delivering 30 J or more to terminate unstable VT and ventricular fibrillation (VF).

## Interpreting an ICD Interrogation

All ICDs can be interrogated noninvasively to obtain the program that describes what the device will do for a given abnormal heart rate and/or to verify that a reported shock was indeed a shock and was delivered appropriately for VT or VF. An ICD interrogation slip is shown in Figure 44-6. Intracardiac electrograms are depicted. From top to bottom, these are the near-field atrial electrogram, the near-field ventricular electrogram, and the far-field electrogram, which represents a closer approximation to the surface ECG. Inspection of this episode shows initial atrial and ventricular depolarizations in a sequence consistent with sinus rhythm. A premature ventricular depolarization follows and initiates VF at a cycle length less than 200 ms. During the episode of VF, the activity depicted in the near-field atrial electrogram is unrelated to that in the near-field ventricular electrogram, consistent with VF. The VF is treated successfully with a 21-J biphasic shock. After the shock, the ensuing bradycardia prompts the device to initiate post-shock AV pacing, which is manifested as a wide-complex ventricular rhythm on the far-field electrogram. Interrogation of the device after a shock is important to document appropriate sensing and treatment of the ventricular arrhythmia.

## Major Indications for ICD Implantation

The major class I indications for ICD implantation as reported by the ACC/AHA/HRS 2008 Guidelines for Device-Based Therapy of Cardiac Rhythm Abnormalities are listed below[4]:

1. Survivors of cardiac arrest caused by VT or VF that has an irreversible cause (class I): A mortality benefit has been demonstrated in the Antiarrhythmics versus Implantable Defibrillator (AVID) trial.[96]
2. Spontaneous sustained VT in the presence of structural heart disease (class I): A mortality benefit for this indication also has been demonstrated in the AVID trial.[96]

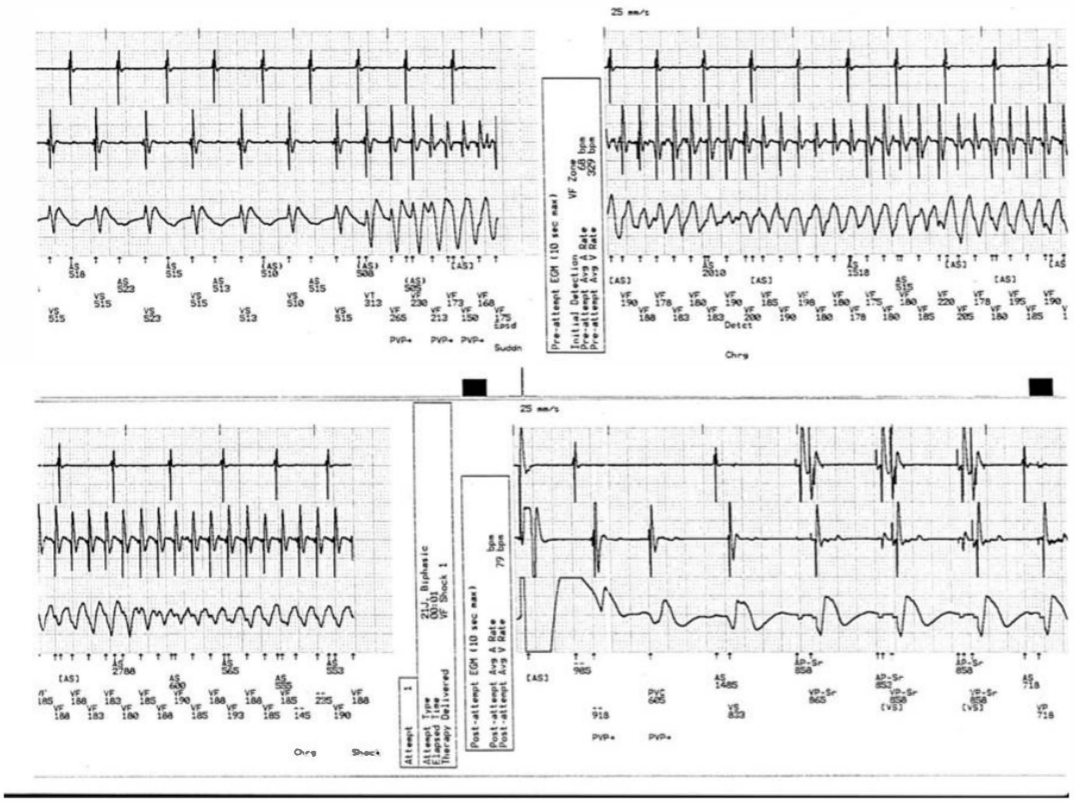

**FIGURE 44-6** ICD interrogation slip. In order from top to bottom, atrial near-field electrogram, ventricular near-field electrogram, and far-field electrogram are shown. Sinus rhythm is followed by a premature ventricular contraction initiating VF (cycle length <200 ms), which resolves with a 21-J biphasic shock and is followed by postshock ventricular pacing. Note that during VF, AV dissociation is present.

3. ICD therapy is indicated in patients with syncope of undetermined origin with clinically relevant, hemodynamically significant sustained VT or VF induced at electrophysiological study.[97]
4. ICD therapy is indicated in patients with LVEF less than 35 percent due to prior myocardial infarction who are at least 40 days post-myocardial infarction and are in NYHA functional class II or III.
5. ICD therapy is indicated in patients with nonischemic dilated cardiomyopathy who have an LVEF less than or equal to 35 percent and who are in NYHA functional class II or III. This recommendation is due to the landmark Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT) which showed a 23 percent reduction in mortality in nonischemic heart failure patients (NYHA class II/III, EF ≤35 percent) who received a prophylactic ICD versus placebo.[51] Of note, the SCD-HeFT trial showed a similar magnitude of survival benefit whether the cardiomyopathy was of ischemic or nonischemic etiology.[50,51]
6. ICD therapy is indicated in patients with LV dysfunction due to prior myocardial infarction who are at least 40 days postmyocardial infarction, have an LVEF less than 30 percent, and are in NYHA functional class I.[52] This indication is based on the Multicenter Automatic Defibrillator Implantation Trial II (MADIT-II), in which patients with a prior myocardial infarction and an EF less than or equal to 30 percent who received an ICD had 31 percent lower mortality after 20 months of follow-up than did those given conventional therapy.[98] An important task that lies ahead is to find more specific ways to risk stratify this large population, as the economic burden of having all patients in this group receive ICDs would be quite large.
7. ICD therapy is indicated in patients with nonsustained VT due to prior myocardial infarction, LVEF less than 40 percent, and inducible VF or sustained VT at electrophysiological study.[99]

## Defibrillators in Cardiac Surgery Patients

When considering therapy with an ICD for patients referred for cardiac surgery or with recent cardiac surgery, the following points should be considered. First, revascularization

constitutes excellent antiarrhythmic therapy. The CABG-Patch trial[100] randomized 900 patients scheduled for CABG, EF equal to or less than 35 percent, and an abnormal signal-averaged ECG (SAECG) indicates an increased arrhythmia risk. Even with an overall 42-month mortality rate of 24 percent as would be expected for higher risk patients, there was no significant decrease in mortality associated with ICDs after 32 ± 6 months of follow-up. Many trials showing benefit for ICDs, such as the AVID,[96] MADIT-I,[99] and MADIT-II[98] trials, excluded patients referred for CABG and those with recent CABG. For example, MADIT-II excluded patients who had undergone CABG within 3 months.[98] As a result, patients with EF equal to or less than 30 percent shortly after CABG do not meet the criteria for an ICD on the basis of the MADIT-II study. Of note, a post hoc analysis of 281 patients excluded from the AVID trial because they were referred for CABG showed a trend for ICD benefit compared with antiarrhythmic drugs.[96] However, these results are difficult to interpret in light of the post hoc analysis, nonrandomized patients, and lack of statistical significance.

In regard to ICDs in early postsurgical patients, it is important to note that an ICD does not constitute acute therapy for sustained ventricular arrhythmias. On the contrary, ICDs are meant to be a mode of chronic primary or secondary prevention of sudden death associated with ventricular arrhythmias. If a postsurgical patient is having frequent sustained ventricular arrhythmias, that patient should be rendered arrhythmia free with medical therapy first. The drug of choice in patients with recent CABG is usually amiodarone if there are no contraindications, although other antiarrhythmic drugs may be considered. If amiodarone is chosen and the patient has breakthrough ventricular arrhythmias, additional IV loading doses of amiodarone are frequently effective. In a postsurgical patient who already has an ICD, there still may be a need for external defibrillation. Since most devices assess the need for therapy on the basis of heart rate, a patient may have symptomatic VT at a rate that is below the threshold for initiating automated therapy (particularly if the patient has been on an antiarrhythmic drug such as amiodarone). In patients referred for both cardiac surgery and an ICD, the ICD should be implanted after the surgery due to the potential for lead displacement during surgery.

Finally, patients with a history of cardiac surgery may be referred at some point for CRT (discussed earlier) for class III or IV heart failure associated with a dilated cardiomyopathy (EF less than 35 percent) and intraventricular conduction delay. Results from the COMPANION trial demonstrated a 43 percent reduction in mortality compared with optimal medical therapy in patients who met all the criteria and received a combined defibrillator and biventricular pacemaker.[47] As a result, such patients should be considered for an ICD in addition to CRT. Patients who meet the implant criteria for a CRT device and are referred for cardiac surgery may be considered for LV lead implantation to obviate the later potential need for transvenous placement via the coronary sinus.

## DISCLAIMER

Dr. Ronald Berger had no input into formulating the questions due to his association with the ABIM.

## PACEMAKER AND DEFIBRILLATOR THERAPY IN CARDIAC SURGERY PATIENTS BOARD REVIEW QUESTIONS (CHAPTER 44)

1. Which of the following principles apply to the SA node and AVN?
   A. They are fast-response tissues with a baseline membrane potential of −90 mV.
   B. The SA node is a discrete endocardial structure that is easily damaged.
   C. In most individuals the majority of the blood supply to the SA and AVNs comes from the left circumflex artery.
   D. Depolarization of the SA and AVNs depends largely on L-type calcium currents.
   E. The conduction velocity of the SA and AVNs is much faster than the infranodal conduction system.

2. Which of the following is *not* a class I indication for a PPM?
   A. Sinus node dysfunction with symptomatic bradycardia.
   B. AVB in symptom-free patients in AF with pauses >5 seconds.
   C. Asymptomatic LAFB and first degree AVB.
   D. Third degree AVB that results from required drug therapy for medical conditions.
   E. Alternating LBBB and LBBB.

3. All of the following statements about device programming are true *except*:
   A. DDI mode will trigger a ventricular depolarization on the basis of atrial activity.
   B. Patients with pacemakers who are pacemaker dependant should be programmed asynchronously before surgery.
   C. Potential interaction between the device and an electromagnetic field include inability of the device to deliver pacing or shocks, lead-tissue interface damage, changes in pacing behavior, electrical reset to the backup pacing mode, or inappropriate implantable cardioverter-defibrillator (ICD) therapies.
   D. Electromagnetic interference has been reported with TENS units.
   E. Mode switching usually occurs in the setting of atrial tachyarrhythmias and avoids ventricular tracking of rapid atrial beats.

4. A 47-year-old man with an ischemic cardiomyopathy and prior dual chamber ICD implantation presents with a device erosion. The device was implanted 16 months prior to presentation and he is not pacemaker dependant. According to the AHA/HRS Consensus document, proper management includes:
   A. Extraction of the generator and capping the leads followed by a trial of prolonged antibiotics.
   B. Extraction of the generator and both leads in the EP lab with immediate reimplantation of a device on the contralateral side.
   C. Extraction of the generator and both leads in the operating room with cardiac surgery backup readily available.
   D. Wound washout and revision with plastic surgery and prolonged antibiotics.
   E. Generator and lead extraction in the operating room with cardiac surgery backup followed by placement of an epicardial defibrillator patch.

5. A 65-year-old woman with a non-ischemic cardiomyopathy and EF 25 percent presents to your office complaining of dyspnea with mild activity, fluid retention, and weight gain despite optimal medical management. Her ECG shows sinus rhythm with a LBBB. Which of the following statements outlines the best course of action?
   A. Refer her for a single chamber ICD and consider upgrade to a CRT device based upon the results of a dyssynchrony echocardiogram.
   B. Refer her for a CRT device without defibrillator therapy.
   C. Refer her for a CRT-D device with a coronary sinus lead.
   D. Refer her for a CRT-D device with a robotically placed epicardial LV pacing system.
   E. Refer her for an LV assist device.

## ANSWERS

1. **Answer: D.** The baseline membrane potential of fast-response tissue is −90 mV and the peak is +20 (Fig. 39-1). The depolarization of fast-response tissues such as the atria, the bundle of His, bundle branches, and Purkinje fibers is due to an inward sodium current, whereas repolarization of those tissues is due primarily to outward potassium currents. In slow-response tissues such as the sinus node and the AVN, the baseline is about −70 mV and depolarization depends primarily on the L-type calcium current. The SA node is a diffuse and robust subepicardial structure that is surrounded by connective tissue. In most individuals, the majority of the blood supply to the SA and AVNs is from the RCA.
2. **Answer: C.** PPM implantation is not indicated for fascicular block with first degree AVB without symptoms (class III indication). All of the other choices are class I indications.
3. **Answer: A.** The DDI mode is dual-chamber, dual-sensed inhibition of depolarization. Unlike the DDD mode, DDI will not trigger a ventricular artificial depolarization on the basis of atrial activity. The only scenario in which the ventricular lead will trigger an artificial depolarization occurs when the intrinsic ventricular rate is below a programmed threshold.
4. **Answer: C.** Device erosion is a class I indication for complete generator and lead removal. Leads older than a year should be removed in the operating room with cardiac surgery backup. In a patient that is not pacemaker dependant, a course of antibiotics should be completed without additional hardware in place before reimplantation on the contralateral side.
5. **Answer: C.** This patient meets SCD-HeFT criteria for implantation of a primary prevention ICD. Based upon the results of the COMPANION trial, the FDA has approved the use of devices that combine an ICD and a biventricular pacemaker in patients who meet criteria for CRT.

# Surgical Treatment of Chronic Pulmonary Thromboembolic Disease

*Michael M. Madani*
*Stuart W. Jamieson*

## KEY CONCEPTS

- Epidemiology
  - The precise incidence of pulmonary embolism (PE) is unknown; it is estimated to be in the range of 1 to 3 in 1000 individuals. Approximately 75 percent of autopsy-proven PEs are not detected clinically. PE is particularly common in hospitalized elderly patients.
- Pathophysiology
  - PE is usually an embolic manifestation of deep venous thrombosis (DVT), which is caused by venous stasis, vein wall injury, and hypercoagulopathy.
  - Other etiologies include malignancy, chronic indwelling central venous catheters, pacemaker leads, and spontaneous thromboses.
  - Emboli become lodged in the pulmonary artery bed and lead to pulmonary vascular hypertension by several proposed processes: redirected pulmonary blood flow, neurovascular perturbation, and hormonal changes.
- Clinical features
  - Chronic thromboembolic pulmonary hypertension (CTEPH) presents insidiously with vague symptomatology. Suspicion should be raised when signs and symptoms for DVT (e.g., leg swelling, lower extremity venous stasis changes, chest pain, hemoptysis) are encountered.
  - The most common symptoms associated with pulmonary hypertension are exertional dyspnea, presyncope/syncope, and nonspecific chest pain or pressure.
  - The physical signs of CTEPH are related to right heart failure, including a large A wave progressing to a predominant V wave component in the jugular venous pulse. The $S_2$ sound often is narrowly split, and $P_2$ is accentuated; a sharp systolic ejection click may be heard over the pulmonary artery in the second intercostal space. Hypoxia/cyanosis and a right ventricular heave are observed with advanced disease.
- Diagnostics
  - Characteristic findings on plain chest radiography are central pulmonary vascular enlargement, vascular pruning, and right ventricular enlargement.
  - Electrocardiography may demonstrate criteria for right ventricular hypertrophy, including right axis deviation and a dominant R wave in $V_1$.
  - Pulmonary function tests usually reveal minimal changes in lung volume and ventilation with normal or slightly restricted mechanics; the diffusing capacity of the lung for carbon monoxide (DLCO) often is reduced and is the only abnormality on this test.
  - The ventilation perfusion lung scan is essential for diagnosis; an entirely normal scan excludes the diagnosis, whereas most patients with CTEPH demonstrate one or more segmental or larger perfusion defects in otherwise normal lung regions. The magnitude of perfusion defects in chronic thromboembolic disease often underestimates the actual degree of vascular obstruction. A positive scan should prompt a right heart catheterization and pulmonary angiography.
  - High-resolution computed tomography is being used more frequently in the diagnosis of pulmonary thromboembolic disease. However, the gold standard for diagnosis of CTEPH is conventional biplane pulmonary angiography.
- Treatment
  - Medical therapy for CTEPH is limited and generally palliative. New forms of drug therapies are now available for treatment of pulmonary hypertension; however, their benefit in patients with CTEPH is very

limited. Chronic anticoagulation is the mainstay of medical treatment in these patients.
  - Surgical removal of chronic thromboembolic material is the only curative option for patients with CTEPH.
- Outcomes and prognosis
  - Pulmonary endarterectomy (PEA) is a proven procedure for the treatment of CTEPH with excellent long-term results. A 30-year experience at the University of California, San Diego (UCSD) Medical Center indicated an overall operative mortality of 8 percent. This has declined to a current rate of about 2.2 percent.
  - A complication specific to PEA is a reperfusion pulmonary edema that appears to be related to reperfusion of endarterectomized regions.
  - In most treated patients, a significant reduction in pulmonary pressures and pulmonary vascular resistance and a significant increase in pulmonary blood flow and cardiac output are observed immediately and sustained. One year postoperatively, 95 percent of treated patients have improved from New York Heart Association functional class III or IV to functional class I or II.

## INTRODUCTION

Chronic thromboembolic pulmonary hypertension (CTEPH) is a common condition that is severely under diagnosed. The disease is caused by chronic obstruction of the pulmonary vasculature as a result of longstanding pulmonary thromboembolism. Once the diagnosis is made, there is only one curative option: surgical removal. Medical therapy remains palliative at best, and lung transplantation for this condition is outdated. Pulmonary endarterectomy (PEA) is a curative procedure for the treatment of CTEPH with excellent short- and long-term outcomes, but unfortunately it remains an uncommonly performed operation.

Acute pulmonary embolism (PE) is one of the more common cardiovascular diseases affecting Americans. Despite clinical and statistical evidence of progression of the disease in survivors, the majority of patients continue to be misdiagnosed. Perhaps one contributing issue is the fact that there are no specific signs and symptoms associated with this condition. Furthermore, most patients do not have a definitive history of deep vein thrombosis (DVT) or acute PE. The vague nature of symptoms, including dyspnea on exertion and occasional angina-like chest pains, coupled with lack of awareness among common practitioners, makes the diagnosis quite difficult; unfortunately these patients often progress to severe degrees of pulmonary hypertension and right heart failure before a diagnosis is established and treatment strategy is sought.

The precise incidence of PE remains unknown, but there are some legitimate estimates. It is estimated that acute PE occurs in about 1 person out of 1000,[1,2] which puts the annual incidence of acute PE at about 300,000 in the United States alone. The majority of patients with acute PE will resolve their clots with conventional treatments. However, it is estimated that about 3.8 percent of affected patients will go on to develop chronic pulmonary hypertension by 2 years.[1] This is, however, a low estimate, since in 70 to 80 percent of patients where the primary cause of death was PE, a premortem diagnosis was unsuspected.[3,4] The disease is particularly common in hospitalized elderly patients. Of hospitalized patients who develop PE, 12 to 21 percent die in the hospital, and another 24 to 39 percent die within 12 months.[5–7] Another unrecognized subgroup of patients comprises those with intracardiac catheters, shunts, or leads. The true incidence of chronic thromboembolic disease in these patients is unknown, but clearly these devices carry an inherent risk which is usually overlooked by the implanting physicians.

The mainstay of treatment of patients with DVT and acute PE is medical management. There are few indications for surgical intervention in the acute setting and they are specific to patients who have suffered a massive embolus that causes life-threatening acute right heart failure and severe hemodynamic compromise. The presence of large embolic material in the right atrium or right ventricle evidenced by echocardiography in the setting of severe right heart failure and hemodynamic compromise is another instance where surgery would be indicated. These indications are, however, few and far between. In contrast, in the chronic form of this disease, the only treatment is the surgical removal of the thromboembolic material with PEA. The role of medical therapy in these patients remains unclear and may be limited to patients with residual pulmonary hypertension after endarterectomy. For the most part, medical management is only palliative and does not address the obstructive nature of this disease. The only other potential surgical cure is transplantation. However, lung or heart–lung transplantation as a surgical cure for this condition is an outdated form of therapy and should be considered an inappropriate use of resources that yields less than satisfactory results.

The prognosis for patients with pulmonary hypertension is poor, and it is worse for those who do not have intracardiac shunts. Thus, patients with primary pulmonary hypertension and those with pulmonary hypertension secondary to PE fall into a higher risk category than those with Eisenmenger syndrome, and have a higher mortality rate. In fact, once the mean pulmonary arterial pressure in patients with thromboembolic disease reaches 50 mm Hg or more, the 3-year mortality approaches 90 percent.

Regardless of the exact incidence or the circumstances, it is clear that acute embolism and its chronic relation, fixed chronic thromboembolic occlusive disease, are both much more common than generally appreciated and are

significantly under diagnosed. Calculations extrapolated from mortality rates and the random incidence of major thrombotic occlusion found at autopsy would support a postulate that more than 100,000 people in the United States currently have pulmonary hypertension that could be relieved by operation. The procedure appears to be permanently curative, but fewer than 200 of these are performed annually; most of them at the authors' center, the University of California, San Diego (UCSD). This chapter provides an overview of the pathophysiology of this disease and outlines the surgical management as it is performed at UCSD.

## PATHOPHYSIOLOGY

In 1856 Rudolf Virchow made the association between DVT and PE and suggested that the causes of DVT were related to venous stasis, vein wall injury, and hypercoagulopathy. This triad of etiologic factors remains relevant today and is supported by an ever-growing body of evidence. Although a majority of individuals with chronic pulmonary thromboembolic disease are unaware of a precedent thromboembolic event and give no history of DVT, the foundation of most cases of unresolved PE is based on acute embolic episodes. Why some patients have unresolved emboli is not certain, but a variety of factors must play a role, alone or in combination.

In some cases, the volume of acute embolic material may overwhelm the lytic mechanisms. In other cases, total occlusion of a major arterial branch may prevent lytic material from reaching, and therefore dissolving, the embolus completely. Recurring emboli may not be able to be resolved. The embolic material may be made of substances that cannot be resolved by normal mechanisms (already well-organized fibrous thrombus, fat, or tumor). In some patients, the lytic mechanisms themselves may be abnormal, and other patients may have a propensity for thrombus formation or a hypercoagulable state.

Synchronized preservation of the fluidity of blood and the integrity of the vascular system entails a balance between blood pro- and anticoagulants. Some patients have deficiencies in natural anticoagulants. Three uncommon familial deficiencies associated with venous thrombosis are deficiencies in antithrombin, protein C, and protein S. Antithrombin is a natural plasma protease that inhibits thrombin after it is formed and, to a lesser extent, before it is formed. Antithrombin is also the cofactor that is accelerated 1000-fold by heparin. Protein C is a potent inhibitor of factor V and platelet-bound factor VII and requires protein S as a cofactor for anticoagulant activity. Both protein C and S are vitamin K–dependent zymogens that are activated by thrombin and accelerated by thrombomodulin produced by endothelial cells.

A much more common coagulation deficiency that results from a mutation of factor V (factor V Leiden) that prevents its degradation by protein C has been described and is present in approximately 6 to 7 percent of study populations of Swedish and North American males.[8–11] Both the homozygous and heterozygous mutants are strongly associated with venous thrombosis and PE but are not associated with stroke, myocardial infarction, and other manifestations of arterial thrombosis.[11,12]

The presence of the lupus anticoagulant, which is an acquired immunoglobulin G (IgG) or IgM antibody against prothrombinase, increases the likelihood of venous thrombosis.[12] The disease may be associated with lupus-like syndromes, immunosuppression, or the intake of specific drugs, such as procainamide.

In most cases, regardless of the etiology of the embolus, after the clot becomes wedged in the pulmonary artery, one of two processes occurs[13]: (1) organization of the clot proceeding to canalization, producing multiple small endothelialized channels separated by fibrous septa (i.e., bands and webs) or (2) complete fibrous organization of the fibrin clot, leading to a solid mass of dense fibrous connective tissue totally obstructing the arterial lumen.

In addition to the usual pattern of venous thrombosis and subsequent embolization, usually from the legs or pelvis, there are other special circumstances that may lead to PEs. Chronic indwelling central venous catheters and pacemaker leads sometimes are associated with PEs. Rare causes include tumor emboli, and tumor fragments from stomach, breast, and kidney malignancies, which have been demonstrated to cause chronic pulmonary arterial occlusion. Right atrial myxomas may also fragment and embolize.

In addition to the embolic material, a propensity for thrombosis or a hypercoaguable state may result in spontaneous thrombosis within the pulmonary vascular bed, or encourage proximal propagation of thrombus after an embolus. Whatever the predisposing factors to residual thrombus within the vessels, the final genesis of the resultant pulmonary vascular hypertension may be complex. With the passage of time, the increased pressure and flow as a result of redirected pulmonary blood flow in the previously normal pulmonary vascular bed can create a vasculopathy in the small precapillary blood vessels similar to that seen with Eisenmenger syndrome.

Factors other than the simple hemodynamic consequences of redirected blood flow are probably also involved in this process. For example, after a pneumonectomy, 100 percent of the right ventricular output flows to one lung, yet little increase in pulmonary pressure occurs, even with follow-up to 11 years.[14] In patients with thromboembolic disease, however, one frequently detects pulmonary hypertension even when less than 50 percent of the vascular bed is occluded by thrombus. It thus appears that sympathetic neural connections, hormonal changes, or both might initiate pulmonary hypertension in the initially unaffected pulmonary vascular bed. This process can occur when the initial occlusion is in the same lung or the contralateral lung.

Regardless of the etiology, the advancement of pulmonary hypertension as a consequence of changes in the previously unobstructed bed is serious, since this process may lead to an inoperable condition. Thus, with accumulating experience in patients with thromboembolic pulmonary hypertension,

the authors increasingly have been inclined toward early operation so as to avoid these changes.

## CLINICAL FEATURES

CTEPH is severely underdiagnosed because there are no specific clinical features. Although the majority of pulmonary thromboembolic material originates from a DVT, more than half of the patients with CTEPH do not have a history of DVT or PE. The clinical history may therefore not be helpful, making the diagnosis even more difficult. Nevertheless, during clinical evaluation, predisposing factors for DVT should be sought, as should a history of leg swelling, chest pain, hemoptysis, or any symptom to indicate episodes of PE.

The diagnosis in most patients may be quite difficult since the onset of the disease is insidious. The most frequent symptom coupled with thromboembolic pulmonary hypertension, as with all other sources of pulmonary hypertension, is exertional dyspnea. This dyspnea is out of proportion to any anomalies found on clinical examination. Similar to complaints of easy fatigability, dyspnea that initially occurs only with exertion is often attributed to anxiety or being "out of shape." Syncope or presyncope (light-headedness during exertion) is another frequent symptom in pulmonary hypertension. Generally, it occurs in patients with more advanced disease and higher pulmonary arterial pressures.

Another relatively common complaint with CTEPH is nonspecific chest pain or chest pressure. These occur in approximately 50 percent of patients with more severe pulmonary hypertension. Hemoptysis can occur in all forms of pulmonary hypertension including CTEPH. It probably results from abnormally dilated vessels distended by increased intravascular pressures. Peripheral edema, early satiety, and epigastric or right upper quadrant fullness or discomfort may develop as the right heart fails (cor pulmonale). Some patients with CTEPH present after a small acute pulmonary embolus that may produce acute symptoms of right heart failure. A careful history brings out symptoms of dyspnea on minimal exertion, easy fatigability, diminishing activities, and episodes of angina-like pain or light-headedness. Further examination may reveal signs of pulmonary hypertension.

As is the case with symptoms, the physical signs of CTEPH are far from uniform. The physical examination may be surprisingly unrewarding if right heart failure has not occurred, even if the patient complains of severe dyspnea. Another challenge in diagnosis is that the physical signs of pulmonary hypertension are the same no matter what the underlying pathophysiology.

In the early stages, the jugular venous pulse is characterized by a large A wave. As the right heart fails, the V wave becomes predominant. The right ventricle is usually palpable near the lower left sternal border, and pulmonary valve closure may be audible in the second intercostal space. Occasional patients with advanced disease are hypoxic and slightly cyanotic. Cyanosis, if it is present at all, is usually peripheral and related to low cardiac output. Central cyanosis may be present from a persistent foramen ovale or atrial septal defect with right-to-left shunting. Clubbing is an uncommon finding.

Examination of the chest may be initially normal. Later, jugular venous distension with prominent A and V waves, as described above, may become evident. Auscultation of the chest may reveal some specific and nonspecific anomalies. The second heart sound is often narrowly split and varies normally with respiration; P2 is accentuated. A sharp systolic ejection click may be heard over the pulmonary artery. As the right heart fails, a right atrial gallop usually is present, and tricuspid insufficiency develops. Because of the large pressure gradient across the tricuspid valve in patients with pulmonary hypertension, the murmur is high pitched and may not exhibit respiratory variation. These findings are quite different from those usually observed in patients with tricuspid valvular disease. A murmur of pulmonic regurgitation may also be detected.

One specific sign is a flow murmur, which is heard especially over the back, beneath the scapula. Moser and colleagues[15] pointed out that murmurs are often heard in patients with CTEPH. The murmur is portrayed as maximal over the lung fields, increasing in intensity with inspiration, and frequently spilling beyond the second sound.[15] These murmurs probably result from turbulent flow past a segmental tapering, or it is also conceivable that they correspond to aggressive bronchial flow. An important observation is that these flow murmurs have not been described in patients with primary pulmonary hypertension, the major differential diagnosis for this condition.

Signs of chronic venous stasis may be present in the legs, with skin discoloration, and perhaps with healed varicosities or varicose ulcers. Peripheral edema is variable among patients and, if present, may be especially difficult to detect if the patient has chronic lower extremity venous stasis with or without ulceration.

Thus, the clinical signs and symptoms of CTEPH are not by any means specific and far from uniform. Suspicion for the diagnosis should be raised once the degree of symptomatology is out of proportion to the patient's general condition. Once the suspicion is made, the clinician should then pursue key points in the patient's past history and physical findings that may relate to this condition. The diagnosis, however, is only and finally confirmed with the aid of a broad variety of diagnostic modalities. Table 45-1 summarizes some of the patient characteristics at the authors' center encompassing the last 12 years, from 1998 to 2010, amongst over 1500 patients.

## DIAGNOSTIC MODALITIES

To ensure the diagnosis in patients with CTEPH, a consistent evaluation is recommended for all patients who present with unexplained pulmonary hypertension. The non-specificity of the clinical presentation and symptoms contribute to the

**TABLE 45-1: Preoperative Patient Characteristics in Over 1500 Patients**

| Variable | 1500 Patients (1998–2010) |
|---|---|
| Age (year) | 51.6 ± 15.4 |
| Pulmonary artery pressure (mm Hg) | |
| Systolic | 75.6 ± 18.9 |
| Diastolic | 28.0 ± 9.6 |
| Mean | 45.9 ± 11.5 |
| Pulmonary vascular resistance (dyne/s/cm$^5$) | 814.2 ± 431.5 |
| Cardiac output (L/min) | 4.1 ± 1.4 |
| Tricuspid regurgitant jet (M/s) | 4.2 ± 0.7 |
| In hospital >24 h preoperatively | 344 (22.9) |
| In ICU preoperatively | 27 (1.8) |
| On intravenous inotropes preoperatively | 42 (2.8) |

diagnostic delay that most patients with CTEPH experience. In the authors' center it is common to see patients who have gone undiagnosed for several years, typically for 2 to 3 years.

The workup generally starts with a chest radiograph. Chest radiography may be deceptively normal in the early stages of CTEPH. However, with the development of significant pulmonary hypertension and right heart enlargement, some characteristic findings may tip the examiner toward the diagnosis. Central pulmonary arteries may be enlarged, and the right ventricle may also be enlarged without enlargement of the left atrium or ventricle, unlike mitral stenosis (Fig. 45-1). The chest radiograph may also show either apparent vessel cutoffs of the lobar or segmental pulmonary arteries, or regions of oligemia that suggest vascular occlusion. However, one should keep in mind that despite these classic findings, a large number of patients might present with a relatively normal chest radiograph, even in the setting of severe degrees of pulmonary hypertension. The electrocardiogram demonstrates findings of right ventricular hypertrophy (right axis deviation, dominant R wave in $V_1$).

Pulmonary function tests are necessary to exclude obstructive or restrictive intrinsic pulmonary parenchymal disease as the cause of the hypertension, but generally are not helpful. They reveal minimal changes in lung volume and ventilation; patients by and large have normal or slightly restricted pulmonary mechanics. Diffusing capacity of the lung for carbon monoxide (DLCO) often is reduced and may be the only abnormality on pulmonary function testing.

Most of these patients are hypoxic; room air arterial oxygen tension ranges between 50 and 83 torr, the average being 65 torr.[16] $CO_2$ tension is slightly reduced and is compensated by reduced bicarbonate. Dead space ventilation is increased. Ventilation–perfusion studies show a moderate mismatch with some heterogeneity among various respirator units within the lung and correlate poorly with the degree of pulmonary obstruction.[17]

The ventilation–perfusion lung scan is the essential test for establishing the diagnosis of unresolved pulmonary thromboembolism. An entirely normal lung scan excludes

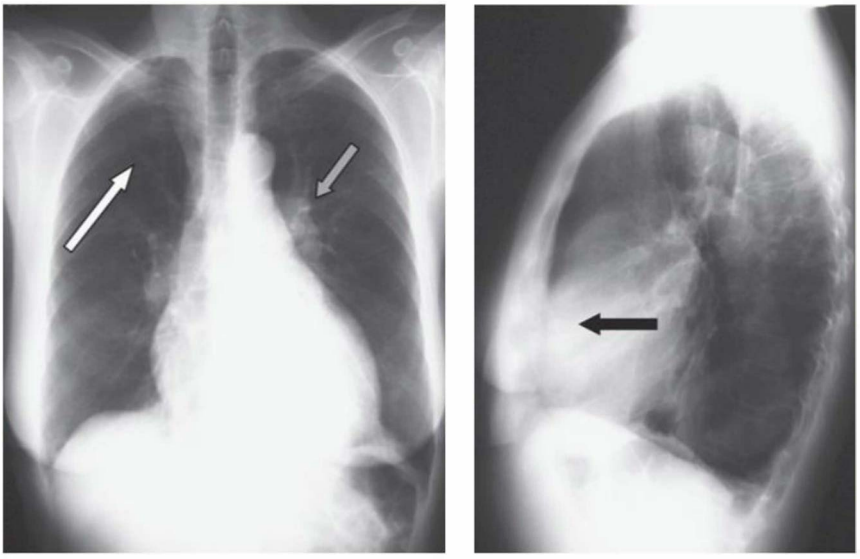

**FIGURE 45-1** Typical chest radiograph of a patient with chronic thromboembolic pulmonary hypertension. Note an enlarged right atrium and right ventricle (*black arrow on the lateral view*), disparity of size between the left and the right pulmonary arteries, and hypoperfusion in several areas of the lung (*white arrows*).

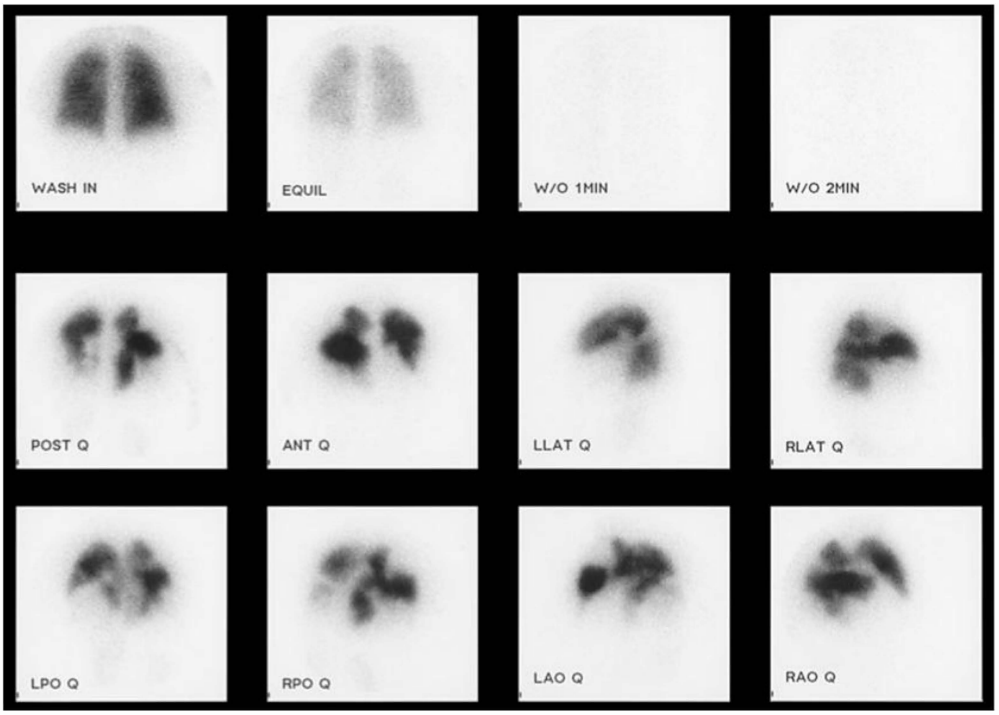

**FIGURE 45-2** Lung ventilation and perfusion study (V/Q scan) in a patient with chronic thromboembolic pulmonary hypertension. Note that the ventilation portion of the study is normal.

the diagnosis of both acute or chronic, unresolved thromboembolism. Patients with CTEPH invariably demonstrate one or more segmental or larger perfusion defects in lung regions that typically have normal ventilation (Fig. 45-2). The usual lung scan pattern in most patients with pulmonary hypertension either is relatively normal or shows diffuse non-uniform perfusion.[18–20] The magnitude of perfusion defects in chronic thromboembolic disease often underestimates the actual degree of vascular obstruction. When subsegmental or larger perfusion defects are noted on the scan, even when they are matched with ventilatory defects, pulmonary angiography is appropriate to confirm or rule out thromboembolic disease.

Right-heart catheterization and pulmonary angiography should be pursued in any patient with suspected chronic thromboembolic disease. Despite advances in computed tomography (CT) and the increasing reliance upon this imaging modality in the evaluation of the pulmonary vascular bed, its role in this population remains somewhat undefined, and pulmonary angiography should still be considered the gold standard in establishing the diagnosis of CTEPH. Organized thromboembolic lesions do not have the appearance of the intravascular filling defects seen with acute pulmonary emboli, and experience is essential for the proper interpretation of pulmonary angiograms in patients with unresolved, chronic embolic disease. Organized thrombi appear as unusual filling defects, webs, or bands, or completely thrombosed vessels that may resemble congenital absence of the vessel (Fig. 45-3).[20] Organized material along a vascular wall of a recanalized vessel produces a scalloped or serrated luminal edge. Because of both vessel-wall thickening and dilatation of proximal vessels, the contrast-filled lumen may appear relatively normal in diameter. Distal vessels demonstrate the rapid tapering and pruning characteristic of pulmonary hypertension (Fig. 45-3).

Historically, angiography in those with pulmonary hypertension has been thought to carry disproportionate risk. The authors have found this not to be the case and, at the authors' institution, pulmonary angiographies are performed daily in these patients with minimal associated risks. Several thousand angiograms in pulmonary hypertensive patients have now been performed at the authors' institution without mortality. Although some risk remains, the benefit of establishing the presence of a treatable cause of the hypertension far outweighs the small risk; pulmonary angiography should be performed whenever there is a possibility that chronic thromboembolism is the etiology of pulmonary hypertension.

In addition to pulmonary angiography, patients over 45 undergo coronary arteriography and other cardiac investigation as necessary. If significant disease is found, additional cardiac surgery is performed at the time of PEA.

In recent years, higher resolution helical CT scans of the chest have been used more frequently in diagnosing pulmonary thromboembolic disease. The presence of large clots in

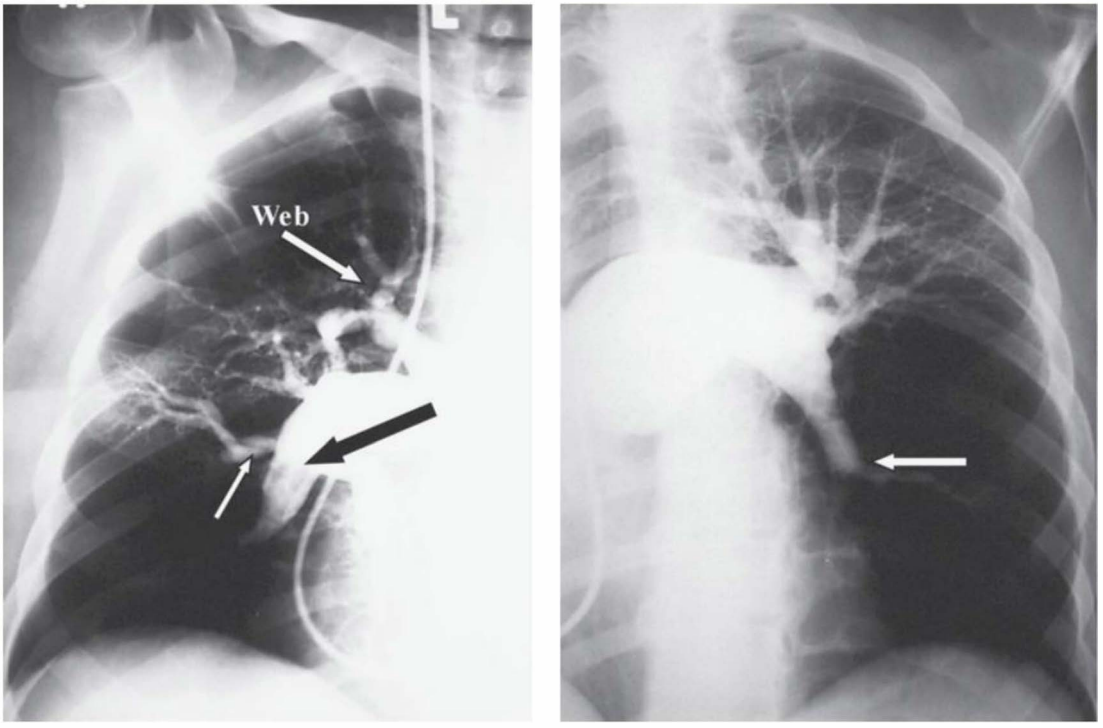

**FIGURE 45-3** Pulmonary angiogram in a patient with chronic thromboembolic pulmonary hypertension. Note the extensive areas of hypoperfusion as a result of complete occlusion, as well as luminal irregularities, webs, bands, and pouches, as shown by arrows.

lobar or segmental vessels generally confirms the diagnosis. CT features of CTEPH include evidence of organized thrombus lining the pulmonary vessels in an eccentric fashion, enlargement of the right ventricle and the central arteries, variation in size of segmental arteries, and parenchymal changes characteristic of pulmonary infarction. In addition, in rare situations in which there are concerns about external compression, or occlusion of main pulmonary arteries is present, CT scans can be helpful in differentiating thromboembolic disease from other causes such as mediastinal fibrosis, lymphadenopathy, or tumors. Although CT scans are considered the gold standard in the diagnosis of acute PE, pulmonary angiography is still the preferred method of diagnosis in chronic pulmonary thromboembolic disease. A patient should never be turned down for surgical treatment without a full evaluation, which includes pulmonary angiography.

## MEDICAL THERAPY

Medical therapy for CTEPH is of limited value and remains palliative at best. In light of the occlusive nature of this disease, there is no curative medical regimen that would alleviate the degree of pulmonary hypertension present in these patients. Right ventricular failure is generally treated with diuretics and vasodilators. Over the past decade, a wide variety of new medical therapies have been developed for the treatment of pulmonary hypertension. These include prostacyclin analogs, phosphodiesterase inhibitors, and endothelium receptor antagonists.[21–23] There has been an increased use of these medical therapies in patients with CTEPH. As a consequence, the authors have been seeing a significant delay in patient referrals, even in patients who have obviously operable disease. In 2010, 45 percent of patients with operable CTEPH referred for and who subsequently underwent surgery at the authors' center were taking one or more pulmonary vasodilator agents. Jensen et al.[24] reported an increased use of these medications from 19.9 percent in 2005 to 37 percent in 2007, in the absence of significant clinical or hemodynamic benefit, while suggesting that this approach resulted in delayed referral for surgery. Further studies are necessary and are currently ongoing to evaluate the efficacy and appropriate role for such therapies. Ultimately, it may be shown that there could be a role for these therapies in patients who have undergone PEA and still have residual pulmonary hypertension. However, these agents are practically useless in the setting of CTEPH, due to the fixed mechanical obstructive nature of the disease. Rarely, patients with CTEPH may experience temporary relief with medical management; this is not curative and symptoms do recur. These patients typically have secondary arteriopathy at the precapillary level and could potentially benefit from medical treatment once the mechanical obstruction has been

removed. In general, medical therapy should be regarded as only supportive, and should not delay referral for surgery. Similarly, the prognosis is unaffected by medical therapy.

Chronic anticoagulation represents the mainstay of the medical regimen. Anticoagulation is primarily used to prevent future embolic episodes, but it also serves to limit the development of thrombus in regions of low flow within the pulmonary vasculature. Inferior vena caval filters are also used routinely to prevent recurrent embolization. If caval filtration and anticoagulation fail to prevent recurrent emboli, immediate thrombolysis may be beneficial, but lytic agents are incapable of altering the chronic component of the disease.

## SURGICAL THERAPY

Surgical removal of the chronic thromboembolic material remains the only curative option for patients with CTEPH. In an experienced center, the procedure can be performed with low operative morbidity and mortality, and can produce tremendous hemodynamic benefit with excellent prognoses. The only other surgical alternative for these patients is transplantation. However, as mentioned earlier, the authors consider transplantation inappropriate for treatment of this disease and believe it to be obsolete in the management of patients with CTEPH. In light of the mortality and morbidity rates of patients on transplant waiting lists, the higher risk of the operation, and the less desirable or inferior survival rate (approximately 80 percent at 1 year at experienced centers for transplantation vs 95 percent for PEA), PEA is clearly the superior choice. Furthermore, PEA appears to be permanently curative, and the issues of a continuing risk of rejection and immunosuppression are not present.

Allison performed the first successful pulmonary "thromboendarterectomy" through a sternotomy, using surface hypothermia in 1960, but only fresh clots were removed.[25] This operation took place 12 days after a thigh injury that led to PE, and an endarterectomy was not performed. Since then, there have been reports of the surgical treatment of chronic pulmonary thromboembolism, but most of the surgical experience in PEA has been reported from the UCSD Medical Center. Braunwald commenced the UCSD experience with this operation in 1970, which now totals almost 2600 cases. The operation described below, using deep hypothermia and circulatory arrest, is now our standard procedure.

### Guiding Principles of the Operation

Once the diagnosis of thromboembolic pulmonary hypertension has been established firmly, the decision for operation is made based on the severity of symptoms and the general condition of the patient. In general, suitable candidates with CTEPH enjoy excellent hemodynamic results, with outstanding long-term prognoses. Early in the PEA experience, Moser and colleagues pointed out that there were three major reasons for considering endarterectomy: hemodynamic, alveolo-respiratory, and prophylactic.

The hemodynamic goal is to prevent or ameliorate right ventricular compromise caused by pulmonary hypertension. The respiratory objective is to improve respiratory function with the removal of a large ventilated but unperfused physiologic dead space. The prophylactic goal is to prevent progressive right ventricular dysfunction or retrograde extension of the obstruction, which might result in further cardiorespiratory deterioration or death. The authors' experience has added another prophylactic goal: the prevention of secondary arteriopathic changes in the remaining patent vessels.

Although the essential techniques of PEA are quite similar to other open-heart operations, several guiding principles are specific for this procedure. For pulmonary hypertension to be a major factor, both pulmonary arteries must be involved substantially. The surgery is therefore always bilateral, although the volume of chronic thromboembolic material may vary significantly between the two lungs. The only reasonable approach to both pulmonary arteries is through a median sternotomy incision. Historically, there were many reports of a unilateral operation, and occasionally this is still performed in inexperienced centers through a thoracotomy. However, the unilateral approach ignores the disease on the contralateral side, subjects the patient to hemodynamic jeopardy during the clamping of the pulmonary artery, and does not allow for good visibility because of the continued presence of bronchial blood flow. In addition, collateral channels develop in chronic thrombotic hypertension not only through the bronchial arteries but also from diaphragmatic, intercostal, and pleural vessels. The dissection of the lung in the pleural space via a thoracotomy incision therefore can be extremely bloody. The median sternotomy incision, apart from providing bilateral access, avoids entry into the pleural cavities and permits the ready institution of cardiopulmonary bypass.

A thorough and successful endarterectomy of the pulmonary arteries can only be performed in a bloodless field and under circulatory arrest. Cardiopulmonary bypass is therefore essential not only to ensure cardiovascular stability when the operation is performed, but also to allow cooling of the patient for periods of circulatory arrest. Exceptional visibility of the pulmonary vasculature is required, and a bloodless field is an absolute requirement to define an adequate endarterectomy plane and to then follow the PEA specimen deep into the subsegmental vessels. Because of the copious bronchial blood flow usually present in these cases, periods of circulatory arrest are necessary to ensure perfect visibility. Again, there have been sporadic reports of the performance of this operation without circulatory arrest. However, it should be emphasized that although endarterectomy is possible without circulatory arrest, a complete and full endarterectomy is not. Without a complete endarterectomy all the way to the distal tail ends of each branch, successful hemodynamic improvement is not achievable, leaving the patients with residual pulmonary hypertension and a subsequent poor prognosis in the short- and long terms.

The authors always initiate the procedure without circulatory arrest; depending on the collateral flow, a variable amount

of dissection is possible before the circulation is stopped, but never complete dissection. The circulatory arrest periods are limited to 20 min, with restoration of flow after each arrest. With experience, the endarterectomy is generally performed with a single period of circulatory arrest on each side.

A true endarterectomy in the plane of the media must be accomplished. It is essential to appreciate that the removal of visible thrombus is largely incidental to this operation. Indeed, in most patients, no free thrombus is present, and on initial direct examination, the pulmonary vascular bed may appear normal to an inexperienced eye. The early literature on this procedure is filled with reports of thrombectomy performed without a complete endarterectomy, and in these cases the pulmonary artery pressures did not improve, often with the resultant death of the patient.

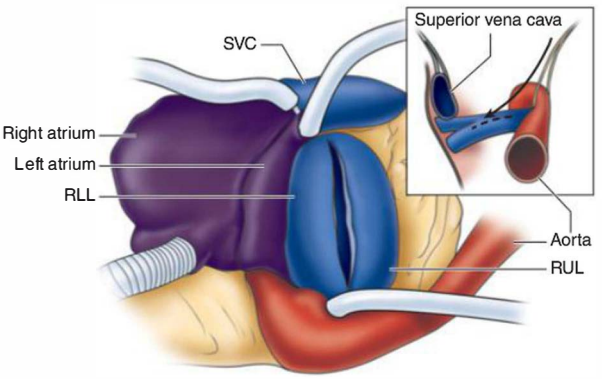

**FIGURE 45-4** Exposure of the right pulmonary artery. The incision is placed between the superior vena cava (SVC) and the aorta (as shown in the insert). It is imperative that the incision toward the right lower lobe artery is made in the middle of the vessel.

## Surgical Techniques

After a median sternotomy is performed, the pericardium is incised longitudinally and attached to the wound edges. Typically the right heart is enlarged, with a tense right atrium and a variable degree of tricuspid regurgitation. There is usually severe right ventricular hypertrophy. These patients are generally quite sensitive to any manipulation of the heart; with critical degrees of obstruction, the patient's condition may become quite unstable.

Anticoagulation is achieved with the use of beef-lung heparin sodium (400 units/kg, intravenously) administered to prolong the activated clotting time beyond 400 s. Full cardiopulmonary bypass is instituted with high ascending aortic cannulation and bicaval cannulation. The cannulae must be inserted into the superior and inferior vena cavae sufficiently to enable subsequent opening of the right atrium. The heart is emptied on bypass, and a vent is placed in the midline of the main pulmonary artery 1 cm distal to the pulmonary valve. This point can also be used to mark the beginning of the left pulmonary arteriotomy.

When cardiopulmonary bypass is initiated, surface cooling with both a head jacket and cooling blanket is begun. Cooling generally takes 45 min to 1 h. When ventricular fibrillation occurs, an additional vent is placed in the left atrium through the right superior pulmonary vein. This prevents atrial and ventricular distension from the large amount of bronchial arterial blood flow that is common in these patients.

The primary surgeon starts the operation on the patient's left side. During the cooling period, some preliminary dissection can be performed, with full mobilization of the right pulmonary artery from the ascending aorta. The superior vena cava is also fully mobilized. The approach to the right pulmonary artery is made medial, not lateral, to the superior vena cava. All dissection of the pulmonary arteries takes place intrapericardially, and neither pleural cavity should be entered. An incision is then made in the right pulmonary artery from beneath the ascending aorta out under the superior vena cava and entering the lower lobe branch of the pulmonary artery just after the take-off of the middle lobe artery (Fig. 45-4). It is important that the incision stays in the center of the vessel and continues into the lower, rather than the middle lobe artery.

A modified cerebellar retractor is placed between the aorta and superior vena cava. Upon opening the pulmonary artery a varying degree of loose thrombus may be present. This material is then removed to ensure good visualization of the vascular bed. It is most important to recognize that (1) an embolectomy without subsequent endarterectomy is quite ineffective, regardless of the amount of thromboembolic material, and (2) in most patients with chronic thromboembolic hypertension, direct examination of the pulmonary vascular bed at operation generally reveals no obvious embolic material. Therefore, to the inexperienced or cursory glance, the pulmonary vascular bed may well appear normal even in patients with severe chronic embolic pulmonary hypertension.

When the patient's temperature reaches 20°C, the aorta is cross-clamped and a single dose of cold cardioplegic solution (1 L) is administered. Additional myocardial protection is obtained with the use of a cooling jacket. The entire procedure is now performed with a single aortic cross-clamp period with no further administration of cardioplegic solution.

If the bronchial circulation is not excessive, the endarterectomy plane can be found during this early dissection. However, although a small amount of dissection can be performed before the initiation of circulatory arrest, it is unwise to proceed unless perfect visibility is obtained because the development of a correct plane is essential. Recognizing the plane is perhaps the most crucial and technically challenging part of the operation.

When blood obscures direct vision of the pulmonary vascular bed, thiopental is administered (500 mg to 1 g) until the electroencephalogram (EEG) becomes isoelectric. In most cases, the EEG is already isoelectric once the core temperature reaches 20°C. Circulatory arrest is then initiated, and the patient is exsanguinated. All monitoring lines to the patient are turned off to prevent the aspiration of air. Snares

are tightened around the cannulae in the superior and inferior vena cavae.

A microtome knife is used to develop the endarterectomy plane posteriorly, because any inadvertent egress in this site could be repaired readily, or simply left alone. Dissection in the correct plane is critical because if the plane is too deep, the pulmonary artery may perforate, with fatal results. If the dissection plane is not deep enough, inadequate amounts of the chronic thromboembolic material will be removed, leaving the patient with residual pulmonary hypertension.

Once the plane is correctly developed, a full-thickness layer is left in the region of the incision to ease subsequent repair. The endarterectomy is then performed with an eversion technique. Because the vessel is everted and subsegmental branches are being worked on, a perforation here will become inaccessible later. This is why the absolute visualization in a completely bloodless field provided by circulatory arrest is essential. It is important that each subsegmental branch is followed and freed individually until it ends in a "tail," beyond which there is no further obstruction. Residual material never should be cut free; the entire specimen should "tail off" and come free spontaneously. Although retrograde cerebral perfusion has been advocated for total circulatory arrest in other procedures, it is not helpful in this operation because it does not provide for a completely bloodless field. Furthermore, with the short arrest times that can be achieved with experience, it is not necessary.

Once the right-sided endarterectomy is completed, circulation is restarted, and the arteriotomy is repaired with a continuous 6-0 polypropylene suture. The hemostatic nature of this closure is aided by the nature of the initial dissection, with the full thickness of the pulmonary artery being preserved immediately adjacent to the incision.

After completion of the repair of the right arteriotomy, the surgeon moves to the patient's right side. The pulmonary vent catheter is withdrawn, and an arteriotomy is made in the left pulmonary artery lateral to the pericardial reflection, avoiding entry into the left pleural space. Additional lateral dissection does not enhance intraluminal visibility, may endanger the left phrenic nerve, and makes subsequent repair of the left pulmonary artery more difficult (Fig. 45-5). The left-sided dissection is virtually analogous in all respects to that accomplished on the right. The duration of circulatory arrest intervals during the performance of the left-sided dissection is subject to the same restriction as for the right.

After completion of the endarterectomy, cardiopulmonary bypass is reinstituted and warming is commenced. The rewarming period generally takes approximately 90 min but varies according to the body mass of the patient.

The pulmonary artery is then closed and the pulmonary arterial vent is replaced. The right atrium is then opened and examined. Any interatrial communication is closed. Although tricuspid valve regurgitation is invariable in these patients and is often severe, tricuspid valve repair is not performed. Right ventricular remodeling occurs within a few days, with the return of tricuspid competence. If other cardiac procedures are required, such as coronary artery bypass or mitral or aortic valve surgery, these are performed conveniently during the systemic rewarming period. Myocardial cooling is discontinued once all cardiac procedures have been concluded. The left atrial vent is removed, and the vent site is repaired. All air is removed from the heart and the aortic cross-clamp is removed.

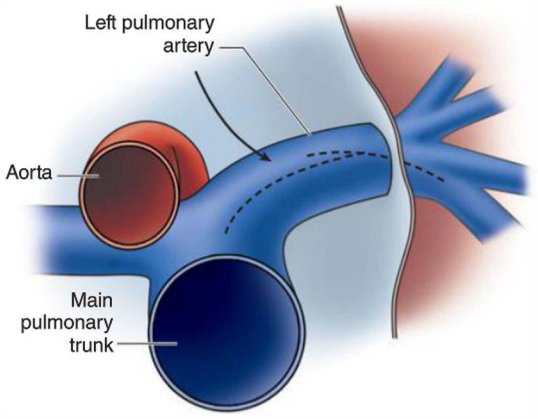

**FIGURE 45-5** Exposure of the left pulmonary artery with its corresponding incision. Note that the incision begins in the mid portion of the main pulmonary artery at the site of the insertion of the pulmonary artery vent.

When the patient has rewarmed, cardiopulmonary bypass is discontinued. Dopamine hydrochloride is routinely administered at renal doses, and other inotropic agents and vasodilators are titrated as necessary to sustain acceptable hemodynamics. The cardiac output is generally high, with a low systemic vascular resistance. Temporary atrial and ventricular epicardial pacing wires are placed.

Despite the duration of extracorporeal circulation, hemostasis is readily achieved, and the administration of platelets or coagulation factors is generally unnecessary. Wound closure is routine. A vigorous diuresis is usual for the next few hours, often a result of the previous systemic hypothermia.

## OUTCOMES/PROGNOSIS

The ages of the patients in our series have ranged from 8 to 86 years. A typical patient will have a severely elevated PVR level at rest, the absence of significant comorbid disease unrelated to right heart failure, and the appearances of chronic thrombi on angiogram that appear to be in balance with the measured degree of PVR. Exceptions to this general rule, of course, occur.

Although most patients have a PVR level in the range of 800 dyne/s/cm$^5$ and pulmonary artery pressures less than systemic, the hypertrophy of the right ventricle that occurs over time makes suprasystemic pulmonary hypertension possible. Therefore, many patients (perhaps 20 percent in the authors' practice) possess PVRs well in excess of 1000 dyne/s/cm$^5$ and suprasystemic pulmonary artery pressures. There is no

**TABLE 45-2: Preoperative/Postoperative Hemodynamic Results and Operating Times in 1500 Patients Since 1998**

| Variable | 1500 Patients (1998–2010) |
|---|---|
| PVR (dyne/s/cm$^5$) | 814.2 ± 431.5 |
| | 281.0 ± 188.5 |
| CO (L/min) | 4.1 ± 1.4 |
| | 5.5 ± 1.5 |
| Systolic PA pressure (mm Hg) | 75.6 ± 18.9 |
| | 45.1 ± 16.5 |
| Mean PA pressure (mm Hg) | 45.9 ± 11.5 |
| | 27.8 ± 9.7 |
| Tricuspid regurgitant velocity (M/s) | 4.2 ± 0.7 |
| | 3.0 ± 0.6 |
| **Operating times** | |
| Total operating room time (min) | 504.0 ± 78.3 |
| Surgical time (min) | 402.5 ± 71.7 |
| CPB time (min) | 243.0 ± 46.0 |
| Cross-clamp time (min) | 99.1 ± 26.5 |
| Circulatory arrest time (min) | 35.6 ± 12.5 |

Data are shown as mean ± standard deviation or number (percentages). Top numbers are preoperative values and bottom numbers are postoperative values. PVR, pulmonary vascular resistance; CO, cardiac output; PA, pulmonary artery; CPB, cardiopulmonary bypass.

upper limit of PVR, pulmonary artery pressure, or degree of right ventricular dysfunction that excludes patients from the operation. Table 45-2 compares the pre- and postoperative hemodynamic results as well as operating times at the authors' center.

As mentioned above, surgeons have become increasingly aware of the changes that can occur in the remaining patent (unaffected by clot) pulmonary vascular bed subjected to the higher pressures and flow that result from obstruction in other areas. Therefore, with the increasing experience and safety of the operation, the authors tend to offer surgery to symptomatic patients whenever the angiogram demonstrates thromboembolic disease. A rare patient might have a PVR that is normal at rest, but elevated with minimal exercise. This is usually a young patient with total unilateral pulmonary artery occlusion and unacceptable exertional dyspnea because of an elevation in dead space ventilation. Surgery, in this circumstance, is performed to reperfuse lung tissue, reestablish more normal ventilation–perfusion relationships (thereby reducing minute ventilatory requirements during rest and exercise), and preserve the integrity of the contralateral pulmonic circulation.

## Thromboembolic Classification and Surgical Outcome

There are four broad types of pulmonary vascular occlusive disease related to thrombus that can be appreciated. These

**FIGURE 45-6** Surgical specimen removed from right and left pulmonary arteries. Fresh thrombus in major arteries indicates of type I disease. Note that removal of only the fresh material leaves a large amount of disease behind. The ruler measures 15 cm.

types are based on the anatomical location of the thromboembolic material as well as vessel wall pathology. This classification allows one to estimate the patient's outcome and prognosis after an endarterectomy.[20,26,27] Type I disease (approximately 11 percent of cases of thromboembolic pulmonary hypertension; Fig. 45-6) refers to the situation in which major vessel clot is present and readily visible on the opening of the pulmonary arteries. As mentioned earlier, all central thrombotic material must be completely removed before the endarterectomy.

In type II disease (approximately 47 percent of cases; Fig. 45-7), no major vessel thrombus can be appreciated. In these cases, only thickened intima can be seen, occasionally

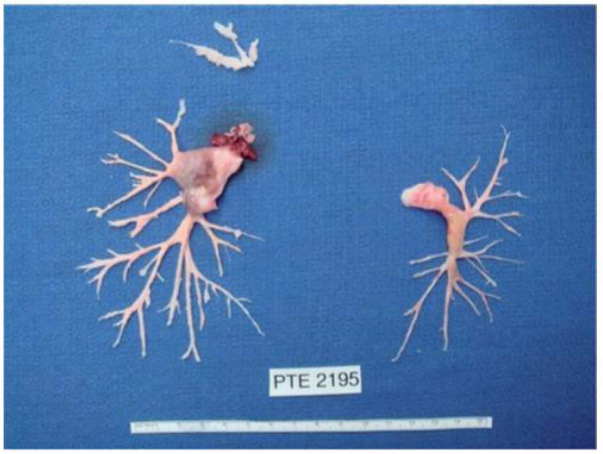

**FIGURE 45-7** Surgical specimen removed from right and left pulmonary arteries indicating evidence of type II disease. Note the extent of dissection down to the tail end of each one of the branches. The ruler measures 15 cm.

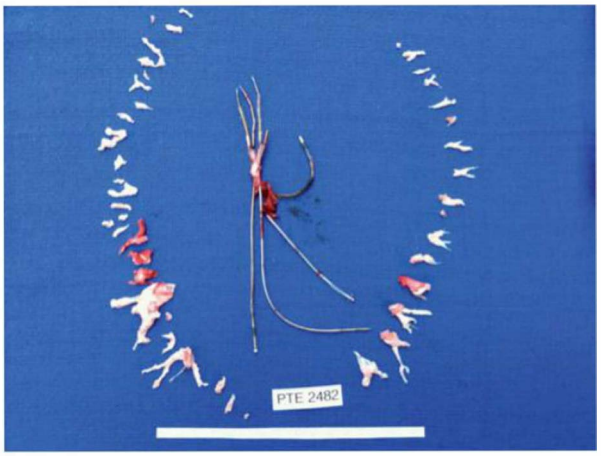

**FIGURE 45-8** Surgical specimen removed from right and left pulmonary arteries in a patient with type III disease secondary to pacemaker leads (*leads also removed as shown*). Note that in this patient the dissection plane has to be developed and raised at each segmental level. The ruler measures 15 cm.

**TABLE 45-3: Jamieson Surgical Thromboembolic Classification**

| Variable | 1500 Patients (1998–2010) |
|---|---|
| Jamieson disease classification (Different types on each side)[a] | |
| No thromboembolic disease or tumor | 33 (2.2) |
| Type I | 160 (10.7) |
| Type II | 710 (47.3) |
| Type III | 472 (31.5) |
| Type IV | 125 (8.3) |
| Jamieson disease classification (Same types on both sides)[b] | |
| Type I | 147 (9.8) |
| Type II | 427 (28.5) |
| Type III | 238 (15.9) |
| Type IV | 31 (2.1) |

Data are shown as number (percentages).

[a]The disease type was different on each side, the patient was categorized with the highest type.

[b]The disease type was similar in both lungs.

with webs, and the endarterectomy plane is raised in the main, lobar, or segmental vessels. Type III disease (approximately 32 percent of cases; Fig. 45-8) presents the most challenging surgical situation. The disease is very distal and confined to the segmental and subsegmental branches. No occlusion of vessels can be seen initially. The endarterectomy plane must be carefully and painstakingly raised in each segmental and subsegmental branch. Type III disease can be associated with presumed repetitive thrombi from indwelling catheters (e.g., pacemaker leads) or ventriculoatrial shunts.

Type IV disease (approximately 8 percent of cases; Fig. 45-9) does not represent primary thromboembolic pulmonary hypertension and is inoperable. It represents microscopic distal arteriolar vasculopathy without visible thromboembolic disease. In this entity, there is intrinsic small vessel disease, although secondary thrombus may occur as a result of stasis. Small-vessel disease may be unrelated to thromboembolic events ("primary" pulmonary hypertension) or occur in relation to thromboembolic hypertension as a result of a high-flow or high-pressure state in previously unaffected vessels similar to the generation of Eisenmenger syndrome. We believe that there may also be sympathetic "cross talk" from an affected contralateral side or stenotic areas in the same lung.

In general, patients with type IV disease will have residual pulmonary hypertension postoperatively, with no change in the levels of postoperative pulmonary vascular resistance (PVR), and unresolved postoperative tricuspid regurgitation. These patients generally require longer inotropic support, ventilatory support, and have longer ICU and hospital stays. They also have higher incidences of postoperative complications and, in fact, comprise the vast majority of the authors' perioperative morbidity and mortality. Table 45-3 indicates the breakdown of patients at the authors' center based on the type of the disease encountered in each lung.

**FIGURE 45-9** Surgical specimen removed from a patient with type IV disease. Note that despite the impressive appearance of the endarterectomy specimen, there are no distal tails. This patient had primary pulmonary hypertension and no change in pulmonary hemodynamics.

## Complications of Pulmonary Thromboendarterectomy

Patients with CTEPH are subject to all of the complications associated with open heart and major lung surgery (mediastinal bleeding, arrhythmias, pneumonia, atelectasis, wound infection, etc.). Table 45-4 summarizes the overall morbidity and mortality of PEA at the authors' center in the last 1500 patients. Furthermore, for comparison purposes, the table also shows the same complications in the last 500 patients. The most notable difference is the decline in mortality, which is now at 2.2 percent. In addition to the complications seen in

**TABLE 45-4: Perioperative Morbidity and Mortality in 1500 Patients Since 1998—Comparison is Made to the Last 500 Patients Since 2006**

| Complication | 1500 Patients (1998–2010) | 500 Patients (2006–2010) |
|---|---|---|
| Reperfusion edema | 202 (13.5) | 51 (10.2) |
| Pneumonia | 141 (9.4) | 49 (9.8) |
| Reoperative bleeding | 56 (3.7) | 19 (3.8) |
| Atrial fibrillation | 50 (3.3) | 22 (4.4) |
| Sepsis | 18 (1.2) | 5 (1.0) |
| Sternal wound infection | 18 (1.2) | 1 (0.2) |
| Hemothorax/pleural effusion | 17 (1.1) | 9 (1.8) |
| Dialysis | 15 (1.0) | 6 (1.2) |
| Pneumothorax | 11 (0.7) | 2 (0.4) |
| Pericardial effusion | 9 (0.6) | 4 (0.8) |
| GI bleeding | 8 (0.5) | 2 (0.4) |
| Sternal dehiscence | 8 (0.5) | 2 (0.4) |
| Chylothorax | 7 (0.5) | 2 (0.4) |
| Cerebrovascular accident | 3 (0.2) | 1 (0.2) |
| Deep venous thrombosis | 3 (0.2) | 1 (0.2) |
| Mortality | 62 (4.1) | 11 (2.2) |

Data are shown as number (percentages).

other forms of open heart and major lung surgery, patients who undergo PEA may develop complications specific to this operation. One such complication is the development of "reperfusion injury." This is a specific complication that is related to localized pulmonary edema. Reperfusion injury is defined as a radiologic opacity seen in the lungs within 72 h of PEA. This loose definition therefore may encompass many causes, such as fluid overload and infection.

True reperfusion injury that has a direct adverse impact on the clinical course of the patient occurs in approximately 13 percent of patients. In its most dramatic form, it occurs soon after operation (within a few hours) and is associated with profound desaturation. Edema-like fluid, sometimes with a bloody tinge, is suctioned from the endotracheal tube. Frank blood from the endotracheal tube, however, signifies a mechanical violation of the blood–airway barrier that has occurred at operation and stems from a technical error. This complication should be managed, if possible, by identification of the affected area by bronchoscopy and balloon occlusion of the affected lobe until coagulation can be normalized.

A common cause of reperfusion pulmonary edema (RPE) is persistent high pulmonary artery pressures postoperatively when a thorough endarterectomy has been performed in certain areas, but a large part of the pulmonary vascular bed is still affected by type IV changes. However, the reperfusion phenomenon is also occasionally encountered in patients after a seemingly technically perfect operation with complete resolution of high pulmonary artery pressures. In these cases, the response may be one of reactive hyperemia after the revascularization of segments of the pulmonary arterial bed that have long experienced no flow. Other contributing factors may include perioperative pulmonary ischemia and conditions associated with high-permeability lung injury in the area of the now denuded endothelium. Fortunately, the incidence of this complication has declined in the authors' series, probably as a result of the more complete and expeditious removal of the endarterectomy specimen that has come with the large experience over the last two decades.

## Management of the Reperfusion Pulmonary Edema

Early measures should be taken to minimize the development of RPE with diuresis, maintenance of the hematocrit, and the early use of peak end-expiratory pressure. Once the capillary leak has been established, treatment is supportive because RPE eventually will resolve if satisfactory hemodynamics and oxygenation can be maintained. Careful management of ventilation and fluid balance is required. The hematocrit is kept high (31–35 percent), and the patient should undergo aggressive diuresis, even if this requires ultrafiltration. The patient's ventilatory status may be dramatically position s ensitive. The $Fio_2$ level is kept as low as is compatible with an oxygen saturation of 90 percent. A careful titration of positive end-expiratory pressure is carried out, with a progressive transition from volume- to pressure-limited inverse ratio ventilation and the acceptance of moderate hypercapnia. The use of steroids is discouraged because they are generally ineffective and may lead to infection. Infrequently, inhaled nitric oxide at 20 to 40 parts/million can improve gas exchange. On rare occasions, the authors have used extracorporeal perfusion support (extracorporeal membrane oxygenator or extracorporeal carbon dioxide removal) until ventilation can be resumed satisfactorily, usually after 7 to 10 days.

## Results of Pulmonary Thromboendarterectomy

PEA is now performed at several major cardiovascular centers around the world; the greatest experience with this operation has been at UCSD Medical Center, where the technique was pioneered and has been refined to its current state over the past two decades. Nearly 2600 pulmonary endarterectomies have now been performed.

The mean age for the authors' patients is 51.6 years, with a range of 8 to 86, and no significant gender difference. In nearly a third of the patients, at least one additional cardiac procedure is generally performed at the time of operation. Most commonly, the concurrent procedure is closure of a patent foramen ovale or atrial septal defect (26 percent) or coronary artery bypass grafting (8 percent).

An immediate reduction of pulmonary pressures and vascular resistance down to normal levels is generally achieved. These hemodynamic accomplishments are usually permanent. The right heart failure rapidly resolves as does the tricuspid regurgitation. These changes are usually evident immediately postoperatively, or as late as a few days later on

follow-up transthoracic echocardiograms. Patients experience a dramatic improvement in their symptoms, and have a very low risk of recurrence so long as they are anticoagulated and have received a preoperative inferior vena caval filter.

An analysis of the authors' data encompassing a time span of 30 years indicates an operative mortality of about 8 percent. However, in a study published in 2003 by the authors,[26] an overall mortality of 4.4 percent was reported. In the authors' most recent series since 2006 including over 500 patients, the mortality has now dropped to 2.2 percent. Furthermore, when considering isolated PEA, without any additional procedures and excluding patients with sarcomas, there has been zero mortality over the past 2 years and in over 260 patients at the author's center. This reflects the learning curve for performing this operation safely and the refinements in surgical technique that have occurred.

With growing experience, the authors are now able to offer this procedure to some very high-risk patients with an overall mortality rate of about 2.2 percent. The majority of patients enjoy dramatic hemodynamic improvement postoperatively. A reduction in pulmonary arterial pressures and resistances to normal levels and a corresponding improvement in pulmonary blood flow and cardiac output are generally immediate and sustained. Echocardiographic studies have demonstrated that, with the elimination of chronic pressure overload, right ventricular geometry rapidly reverts toward normal. Right atrial and right ventricular enlargement regresses. Tricuspid valve function returns to normal within a few days as a result of restoration of tricuspid annular geometry after the remodeling of the right ventricle, and therefore tricuspid repair is not part of the operation. In general, these changes can be assumed to be permanent. Before the operation, more than 95 percent of the patients are in New York Heart Association (NYHA) functional class III or IV; at 1 year after the operation, 95 percent of patients remain in NYHA functional class I or II.[20,28,29]

## SUMMARY

It is increasingly apparent that pulmonary hypertension caused by chronic PE is a relatively common condition, which is under recognized and carries a poor prognosis. Medical therapy is ineffective in prolonging life in these patients and improves symptoms only transiently. The only therapeutic alternative to PEA is lung transplantation. The advantages of endarterectomy over transplantation include a lower operative morbidity and mortality and excellent long-term results without the risks associated with chronic immunosuppression and chronic allograft rejection. The mortality for endarterectomy at the authors' institution is now in the range of 2.2 percent, with sustained benefit. These results are clearly superior to those for transplantation in both the short- and long-term.

Although PEA is technically demanding for the surgeon, requiring careful dissection of the pulmonary artery planes and the use of circulatory arrest, excellent short- and long-term results can be achieved. PEA can now be offered to patients with an acceptable mortality rate and excellent anticipation of clinical improvement. With this growing experience, it has also become clear that unilateral PEA is obsolete and that circulatory arrest is an essential measure.

Despite an increase in awareness over the past two decades, and a continuous effort in education through publications and presentations, the principal difficulty in treating CTEPH is the lack of recognizing the condition. Increased understanding of both the prevalence of this condition and the possibility of a surgical cure should give more patients an opportunity for relief from this debilitating and ultimately fatal disease.

## SURGICAL TREATMENT OF CHRONIC PULMONARY THROMBOEMBOLIC DISEASE BOARD REVIEW QUESTIONS (CHAPTER 45)

1. What percentage of patients with acute PE will go on to develop CTEPH?
   A. 15 to 20 percent
   B. 10 to 15 percent
   C. 5 to 10 percent
   D. 3 to 5 percent
   E. Less than 2 percent

2. Once the mean pulmonary artery pressure exceeds 50 mm Hg, the 3-year mortality is approximately:
   A. 10 percent
   B. 20 percent
   C. 40 percent
   D. 75 percent
   E. 90 percent

3. Which of the following is the gold standard for diagnosing CTEPH?
   A. Pulmonary function testing
   B. Ventilation–perfusion scan
   C. Pulmonary angiography
   D. Transesophageal echocardiography
   E. CT angiography

4. A 48-year-old male is diagnosed with severe pulmonary hypertension secondary to chronic thromboembolic disease. The pulmonary pressures are suprasystemic and the PVR exceeds 1000 dyne/s/cm$^2$. The V/Q scan is severely abnormal with multiple large bilateral perfusion defects. The pulmonary angiogram shows complete occlusion of the bilateral lower lobes as well as webs in the upper lobe branches. Which of the following is the best course of action?
   A. Continue anticoagulation and diuretic therapy
   B. Continue anticoagulation and diuretic therapy; add medical therapy for pulmonary hypertension
   C. Continue anticoagulation and diuretic therapy; add medical therapy for pulmonary hypertension; reassess pressures in 6 months
   D. Proceed with surgical therapy
   E. Decline further therapy due to irreversible pulmonary hypertension

5. Which of the following is the correct technique for PEA?
   A. Median sternotomy, cardiopulmonary bypass, moderate hypothermia with low flow during pulmonary endarterectomy
   B. Thoracotomy with femoral bypass if necessary and periods of low flow during endarterectomy
   C. Median sternotomy, cardiopulmonary bypass, and periods of deep hypothermic circulatory arrest during endarterectomy
   D. Thoracotomy with femoral cardiopulmonary bypass and periods of deep hypothermic circulatory arrest during endarterectomy of the distal vessels
   E. Median sternotomy, cardiopulmonary bypass, inflow occlusion of pulmonary arteries to allow bloodless field during endarterectomy

## ANSWERS

1. **Answer: D.** It is estimated that about 3 to 5 percent of patients that survive an acute PE will develop pulmonary hypertension as the result of chronic thromboembolic disease.
2. **Answer: E.** Prognosis for pulmonary hypertension is quite poor and 3-year mortality reaches 90 percent once the mean pulmonary artery pressure reaches 50 mm Hg.
3. **Answer: C.** Pulmonary angiography is the definitive test for the proper diagnosis of CTEPH, as it defines anatomic features and establishes the degree of pulmonary hypertension.
4. **Answer: D.** The patient has chronic thromboembolic pulmonary hypertension and further medical intervention is unlikely to be effective. Surgical intervention is indicated.
5. **Answer: C.** In order to access both lungs and perform a complete distal endarterectomy into the segmental and subsegmental branches, median sternotomy with full cardiopulmonary bypass is required. Periods of deep hypothermic circulatory arrest provide the necessary bloodless field during the endarterectomy.

# Role of Surgery in Management of Hypertrophic Cardiomyopathy

*Hartzell V. Schaff*

**KEY CONCEPTS**

- Hypertrophic cardiomyopathy (HCM) can be defined as left ventricular hypertrophy in the absence of an underlying cause (e.g., hypertension, aortic stenosis). Left ventricular outflow tract obstruction (LVOTO) results from septal hypertrophy combined with systolic anterior motion of the mitral valve, which also produces variable degrees of mitral regurgitation.
- The distribution of left ventricular hypertrophy is variable in patients with HCM. The appearance and severity of the hypertrophy do not correlate with genotype; multiple ventricular morphologies may be found in the same family. The most common pattern of hypertrophy is diffuse involvement of the ventricular septum.
- Myocardial fiber disarray is a characteristic feature of HCM.
- Although coronary arteries are larger than normal in patients with HCM and basal coronary flow is increased at rest, coronary flow reserve is decreased in symptomatic HCM patients.
- Two-dimensional and Doppler echocardiography is essential in the diagnosis of HCM. Cardiac MRI is useful in identifying regions of left ventricular hypertrophy not easily seen with echocardiography, specifically the anterolateral free wall and apex, and the presence and severity of myocardial fibrosis.
- Symptoms in HCM patients are often associated with the development of LVOTO.
- Transaortic septal myectomy is indicated in HOCM patients who continue to have limiting symptoms despite medical treatment (i.e., β-blockade, calcium antagonists, disopyramide). Mitral valve replacement is reserved for patients with intrinsic leaflet abnormalities that cannot be repaired.
- Adequate septal myectomy usually yields 3 to 12 g of muscle. Intraoperative simultaneous aortic and left ventricular pressure measurements can be used to confirm complete relief of LVOTO after septal myectomy. The most common cause of inadequate myectomy is failure to extend the myectomy far enough toward the cardiac apex.
- Unroofing of coronary artery muscle bridges is performed selectively, particularly in young patients and those experiencing anginal symptoms.
- Mortality risk with septal myectomy is less than 1 percent in experienced centers with over 90 percent of patients experiencing improvement of at least two functional classes. Late recurrence of large resting left ventricular outflow tract gradients is very uncommon after successful myectomy.
- Alcohol septal ablation is an alternative to myectomy in high-risk HCM patients. It has been associated with an 11-percent incidence of complete heart block requiring permanent pacemaker and a 1.5-percent hospital mortality.

## INTRODUCTION

Hypertrophic cardiomyopathy (HCM) may be defined as left ventricular (LV) hypertrophy in the absence of an underlying cause such as systemic hypertension or valvular aortic stenosis.[1] Left ventricular outflow tract obstruction (LVOTO) is caused by septal hypertrophy combined with abnormal systolic anterior motion (SAM) of the mitral valve, and this, in turn, produces variable degrees of mitral valve regurgitation (MR). LVOTO in HCM is distinct in morphology and

prognosis from congenital membranous subaortic stenosis, which is rarely associated with SAM. Some patients with HCM will have symptoms due to mid ventricular obstruction. Hypertrophic obstructive cardiomyopathy (HOCM) is important for surgeons because obstruction may occur in over 70 percent of patients with HCM,[2] and transaortic septal myectomy is highly effective in the management of HOCM.

## Morphology

### DISTRIBUTION OF HYPERTROPHY

As shown in Figure 46-1 distribution of LV hypertrophy is variable in patients with HCM. For example, subaortic stenosis may be associated with diffuse ventricular hypertrophy (Fig. 46-1E), or the hypertrophy may be limited to the septum (asymmetric septal hypertrophy, ASH) (Fig. 46-1B). In other patients, there may be obstruction in the mid-ventricle where hypertrophy of the papillary muscles leads to obstruction of ejection of blood, and in other patients, there may be an apical distribution of hypertrophy (Fig. 46-1F). It is important to note that neither the phenotype of the disease nor the appearance and severity of hypertrophy correlates with genotype; multiple ventricular morphologies may be found in the same family.

### MITRAL VALVE

In the classic form of HOCM, the mitral valve, especially the anterior leaflet of the valve, moves anteriorly during systole, and the posterior leaflet closes against the mid- and free-edge third of the anterior leaflet instead of at the free edge as occurs normally. The free edge of the anterior

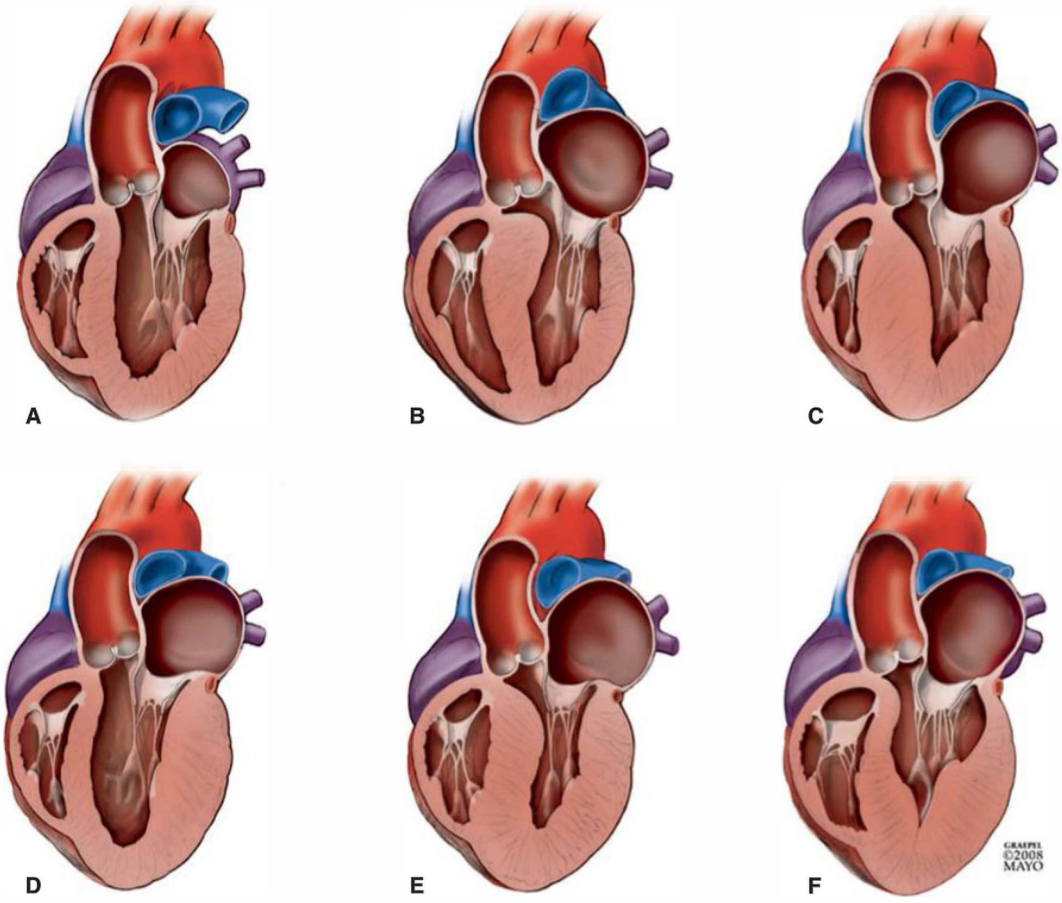

**FIGURE 46-1** Morphologic subtypes of hypertrophic cardiomyopathy. Hypertrophy may be localized t o the basal septum as in panel **B**, diffuse as in panel **E**, or predominantly apical as shown in panel **F**. Normal ventricular morphology is shown in panel **A**. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

leaflet is then displaced upward and narrows the left ventricular outflow tract (LVOT). Anterior displacement of the valve leaflets produces MR of variable degree, and the jet is oriented in a posterolateral direction. MR is an important pathophysiologic component of HOCM and contributes to the symptoms of dyspnea and fatigability. Apposition of the anterior leaflet to the bulging septum produces a contact lesion, a whitish endocardial scar, which is useful in guiding septal myectomy. It is important to note that occurrence of SAM is often dynamic, and provocative maneuvers such as Valsalva, squatting, exercise, and, in some cases, adrenergic stimulation may be necessary to elicit SAM, MR, and LVOTO.

Anomalies of papillary muscles are present in 15 to 20 percent of patients with HCM who undergo myectomy. These abnormalities include anomalous papillary muscles, direct insertion of papillary muscles into the anterior mitral valve leaflet, fusion of the papillary muscle to the ventricular septum or LV free wall, and accessory muscles and accessory anomalous chordae (false cords). In most cases, these abnormalities do not complicate myectomy or contribute to outflow tract obstruction, but in some patients, anomalous papillary muscles, especially those that insert directly into the anterior leaflet, can contribute to outflow tract obstruction.[3]

### CORONARY ARTERIES

Coronary arteries are larger than normal in patients with HCM, and basal coronary flow is increased in the resting state. Coronary flow reserve (CFR), however, is decreased in symptomatic patients with HCM compared with controls, and phasic flow is abnormal with a greater amount of flow during diastole, the presence of flow reversal in systole, and a more rapid deceleration of diastolic blood flow compared with normal patients. Decreased flow reserve is associated with a reduction in coronary resistance, suggesting that the mechanism is not due to narrowing of intramyocardial small arteries or compression of the microcirculation; indeed, the reduction in CFR in patients with HCM may be the result of near maximal vasodilation of the microcirculation in the basal state.

Atherosclerotic coronary artery disease (CAD) is present in approximately 5 to 15 percent of patients with HCM depending upon the population studied. At the Mayo Clinic, significant CAD was detected in half of patients who were selected for coronary angiography, and disease was severe in 26 percent.[4] Survival of HCM patients with obstructive CAD is reduced compared with HCM patients without CAD, and survival is also poorer than in patients without HCM who have comparable CAD and normal ventricular function.

Muscular bridging of the left anterior descending coronary artery (LAD) is not uncommon, occurring in 15 percent of patients with HCM undergoing coronary angiography at our clinic. It is unclear whether bridging of the LAD plays a role in the pathophysiology of the disease and associated symptoms of angina, but for adult patients, risk of death and, in particular, sudden cardiac death, is not increased among patients with HCM with myocardial bridging. In contrast, Yetman and coworkers[5] reported that among children with HCM, systolic compression of the LAD was present in 285 cases and was associated with a greater incidence of chest pain (60 vs 19 percent, $P = 0.04$), cardiac arrest with subsequent resuscitation (50 vs 4 percent, $P = 0.004$), and ventricular tachycardia (80 vs 8 percent, $P < 0.001$). Myocardial ischemia was postulated to be the cause of this poor outcome.

## Histopathology

### MYOCARDIAL FIBER DISARRAY

A characteristic histologic feature of HCM is myocardial fiber disarray, which consists of short runs of severely hypertrophied fibers interspersed by connective tissue. Myocytes show large, bizarre nuclei with degenerating muscle fibers and fibrosis. It is the disorganized whirling of muscle fibers that is characteristic of HCM. Myocardial disarray is not pathognomonic for HCM and may be present in the myocardium for any conditions in which there is pressure overload.

# GENETICS

HCM has a prevalence of 0.2 percent for phenotypically expressed disease. Approximately 60 to 80 percent of cases are familial and the remainder result from de novo mutations.[6] HCM is genetically diverse, involving sarcomeric and nonsarcomeric proteins, and over 400 mutations in over 15 genes have been identified; indeed, double and compound heterozygosity and homozygosity have been reported.[7] Most patients with familial disease have mutations in three protein-encoding genes: β-myosin heavy chain (MYH7) in 35 to 50 percent, myosin-binding protein C (MYBPC3) in 15 to 25 percent, and cardiac troponin T type 2 (TNNT2) in 15 to 20 percent. In current practice, the clinical value of genetic testing is uncertain.

A potential benefit of genetic analysis is the preclinical diagnosis in patients with a family history of SCD or in those carrying a "malignant" mutation that predisposes them to a severe phenotype. Also, it may be useful to know the precise genetic defect in HCM among asymptomatic family members who carry the mutation and might be at risk for SCD.

# PATHOPHYSIOLOGY

## Diastolic Dysfunction

Diastolic dysfunction with elevation of the LV end-diastolic pressure is the principal pathophysiologic feature in HCM. The resulting increase in left atrial and pulmonary venous

pressures accounts for the common symptoms of effort dyspnea and limited aerobic capacity. With worsening diastolic function, LV filling becomes more dependent on atrial contraction, and occurrence of atrial arrhythmias, especially atrial fibrillation (AF), can cause an acute and profound decrease in cardiac output and worsening of symptoms.

LVOTO has a direct effect of increasing end-diastolic pressure and an indirect effect on hemodynamics through the often associated MR. Thus, while surgical myectomy has a minimal immediate effect on overall LV mass, symptoms related to diastolic dysfunction are immediately improved when outflow gradients and MR are relieved. A secondary effect of septal myectomy on diastolic function is regression of hypertrophy.

In some patients, concentric ventricular hypertrophy is so severe that muscle mass encroaches upon the ventricular cavity and reduces normal cavity size. This is particularly striking in patients with the apical form of HCM where the distal one-third to distal one-half of the left ventricle may be obliterated (during diastole and systole) by muscle. Surgical remodeling by apical myectomy may increase end-diastolic volume and thus improve diastolic function.

## Left Ventricular Outflow Obstruction

Surgical treatment of HCM consists primarily of relief of LVOTO. Previously, there was debate on the importance of outflow tract obstruction as a mechanism for symptoms in patients with HCM because of the lability of the finding and the question of catheter entrapment when gradients were measured by invasive catheterization. It is now recognized that outflow obstruction is much more common than previously thought, correlates importantly with development of symptoms, and may negatively influence long-term survival.

Among 320 patients with HCM, Maron found resting outflow tract gradients of ≥50 mm Hg in 37 percent and, more importantly, found exercise-induced gradients (mean 80 ± 43 mm Hg) in an additional 106 patients. Thus, as many as 70 percent of patients with HCM who come to clinical evaluation will have significant outflow tract obstruction.[8] Another important finding in this study was the relative unreliability of the Valsalva maneuver (sensitivity 40 percent) compared with exercise Doppler echocardiography in detecting these dynamic gradients. Latent obstruction can also be documented during hemodynamic catheterization by isoproterenol challenge, and the technique may be useful in patients who are unable to exercise or in patients in whom reliable Doppler echocardiographic parameters cannot be measured.[9]

## Mitral Valve Regurgitation

As is true with outflow gradients, the degree of MR is often dynamic. Symptomatic patients with moderate or severe degrees of MR associated with HOCM are excellent candidates for operation because the MR and associated symptoms (dyspnea and fatigability) are almost always abolished or significantly improved with adequate septal myectomy.

Intrinsic mitral valve disease may contribute to valvular regurgitation in patients with HOCM. Rupture of chordae with resultant leaflet prolapse can precipitate congestive heart failure, and hemodynamics may worsen if HCM is not recognized and patients are managed medically with afterload reduction.

## Echocardiogram

Two-dimensional and Doppler echocardiography is the essential tool for the diagnosis of HCM, providing information on ventricular morphology, hemodynamics, and valve function. The most common pattern of hypertrophy is diffuse involvement of the ventricular septum. In patients with HCM, the average maximal LV-wall thickness is 20 to 22 mm, and in 5 to 10 percent of patients, LV wall thickness is dramatically increased measuring 30 to 50 mm. Morphology of the septum appears to vary according to age, and older patients with HCM often demonstrate a sigmoid configuration.

The echocardiographic findings of increased wall thickness should prompt a search for other causes including systemic hypertension (especially in patients on dialysis), valvular aortic stenosis, and infiltrative and glycogen storage diseases such as cardiac amyloidosis, Fabry's disease, and Friedreich's ataxia.

On continuous-wave Doppler echocardiography, LVOTO is seen as a high-velocity, late-peaking, "dagger-shaped" signal. In patients with low velocity at rest (less than 3 m/s), maneuvers such as Valsalva, inhalation of amyl nitrate, or exercise may demonstrate latent obstruction. Presence and severity of MR can be determined by Doppler color-flow imaging. It is important to differentiate the true outflow tract velocity from the MR jet.

MR that results from SAM is eccentric and directed posterolaterally during late systole. A centrally directed jet should raise suspicion of a primary leaflet abnormality contributing to valve leakage. Preoperative transesophageal echocardiography (TEE) is unnecessary in most patients, but TEE is critically important intraoperatively in assessing the results of myectomy.

## Cardiac MRI

Cardiac MRI is useful in identifying regions of LV hypertrophy not easily recognized by echocardiography, specifically the anterolateral free wall and the apical area. In addition, MRI can detect the presence and severity of myocardial fibrosis that appears to be an important risk factor for subsequent ventricular arrhythmias and sudden cardiac death.

## Invasive Catheterization

In current practice, cardiac catheterization is rarely necessary for the diagnosis of HCM. Coronary angiography is indicated for patients with symptoms of angina and for patients at risk for CAD (strong family history, abnormal lipids, older age) who undergo myectomy. A hemodynamic study with isoproterenol provocation can be useful in identifying patients with labile obstruction gradients that cannot be elicited during echocardiography.

# NATURAL HISTORY

## Symptom Course

The clinical course of HCM is variable, but the onset of symptoms is often associated with development of LVOTO. It is uncertain what causes this in adult patients who have had no gradients until the fourth, fifth, or sixth decade of life. Onset of AF can also precipitate symptoms and predispose to systemic embolism, which occurs in 6 percent of patients.[10] AF is noted in 30 percent of older patients with HCM.

Infective endocarditis may occur with HCM, and the reported incidence is 1.4 cases/1000 person-years. But the important feature is that in virtually all cases of endocarditis, there is LVOTO. Indeed, among HCM patients with obstruction, the incidence of endocarditis is 3.8 per 1000 person-years, or a 4 percent likelihood of developing this complication over 10 years.

## Survival

In the general population, survival of patients with HCM is similar to individuals without disease, and early reports of high mortality in HCM may be explained by excess numbers of high-risk patients included in studies from tertiary referral centers. More recent data indicate that the annual mortality rate of patients with HCM is approximately 1 percent, but there are several important subgroups that have higher risk of cardiac death; indeed, HCM is the most common cause of sudden death among young athletes.

## Obstructed vs Nonobstructed HCM

Until recently, there was uncertainty and debate on the influence of LVOTO on survival of patients with HCM. Convincing studies by Maron et al.,[11] Autore and associates,[12] and Elliot and coworkers[13] have demonstrated a strong correlation between resting outflow gradients and late risk of death. In a longitudinal study of 1101 patients with HCM, Maron et al. reported that patients with outflow tract obstruction (a basal gradient of at least 30 mm Hg) had a risk of death from HCM or symptom progression that was more than four times that observed among patients

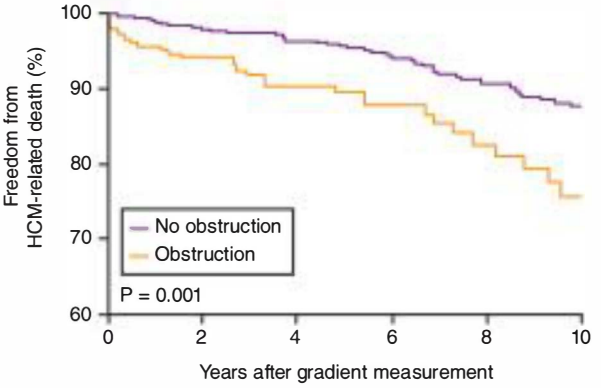

**FIGURE 46-2** Survival of patients with hypertrophic cardiomyopathy with and without obstruction (≥30 mm Hg). This analysis includes only deaths related to HCM. (Reproduced with permission from Maron MS, Olivotto I, Betocchi S, et al. Effect of left ventricular outflow tract obstruction on clinical outcome in hypertrophic cardiomyopathy. *N Engl J Med* 2003;348:295–303. Copyright Massachusetts Medical Society.)

without obstruction (Fig. 46-2). The association of outflow tract obstruction on limiting symptoms and death was independent of other clinical variables. Of note, patients with obstruction and mild symptoms (NYHA class II) were more likely to have progression to severe symptoms or die from heart failure than asymptomatic patients with cardiomyopathy (Fig. 46-3).

An important clinical question is whether the prognosis of asymptomatic HOCM patients with high gradients can be improved by septal reduction. Elliot et al. report that the risk of sudden death is relatively low (<0.4 percent per year) in asymptomatic patients with LVOTO and none

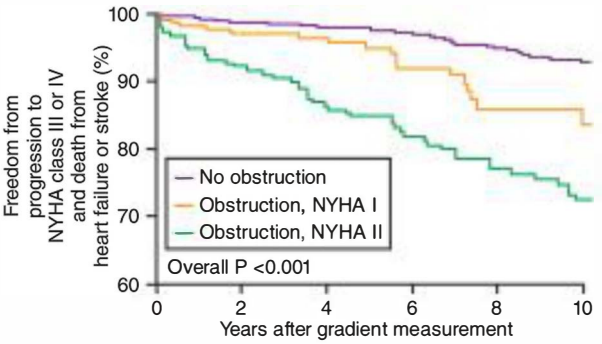

**FIGURE 46-3** Probability of progression to severe heart failure, death, or stroke in patients without obstruction and in patients with outflow tract obstruction stratified by presence or absence of symptoms. (Reproduced with permission from Maron MS, Olivotto I, Betocchi S, et al. Effect of left ventricular outflow tract obstruction on clinical outcome in hypertrophic cardiomyopathy. *N Engl J Med* 2003;348:295–303. Copyright Massachusetts Medical Society.)

of the recognized risk factors for SCD; but their study did demonstrate reduced survival among patients with LVOTO and nonsustained ventricular tachycardia, abnormal exercise blood pressure response, a family history of premature sudden death, unexplained syncope, or severe LV hypertrophy.[13]

The prognosis of patients with latent obstruction is less clear, but a study by Vaglio et al. suggests that the clinical course is similar to patients with resting obstruction.[14] In their series, one-quarter of patients required invasive therapy for relief of symptoms, and the annual mortality was 2 percent per year, a rate higher than that reported for patients with HCM and no LVOTO.

### Use of Implantable Cardioverter-Defibrillator

SCD is a special concern in HCM, and there is debate on the appropriate use of implantable cardioverter-defibrillators (ICDs) for primary and secondary prevention of SCD. Variables that appear to identify patients at increased risk of arrhythmic events include prior cardiac arrest or sustained ventricular tachycardia, a family history of premature sudden death due to HCM, repetitive nonsustained ventricular tachycardia on ambulatory Holter monitoring, massive ventricular hypertrophy (wall thickness greater than 30 mm), and hypotensive response to exercise. Other findings such as myocardial bridging in young patients or myocardial fibrosis detected by cardiac MRI may also increase the risk of sudden death.

Consensus among experts holds that an ICD is strongly warranted for secondary prevention of SCD in patients with prior cardiac arrest or sustained and spontaneously occurring ventricular tachycardia, and should be considered in patients with multiple clinical risk factors and in selected patients with a single major risk factor such as a history of SCD in a close relative. For patients who need an ICD implant and are referred for septal myectomy, we prefer to delay device implantation until the third or fourth day postoperatively and avoid the potential for lead dislocation if the ICD is placed immediately preoperatively.

## SURGICAL TREATMENT

### Indications for Operation

Septal myectomy is, in general, reserved for patients who continue to have limiting symptoms despite medical treatment. Pharmacological therapy usually begins with β-adrenergic blocking agents, which have a negative inotropic effect and may mitigate latent outflow gradients provoked with exercise. β-Blockers are less effective in reducing resting gradients. The calcium antagonist, Verapamil, has been used for patients with nonobstructive and obstructive HCM. The drug may improve ventricular relaxation and decreased LV contractility, but hemodynamic and electrophysiologic side effects limit long-term use. Disopyramide has negative inotropic effects and is a type I-A antiarrhythmic agent that can improve symptoms by reducing resting gradients. However, this drug also has side effects including dry mouth and eyes, constipation, and difficulty in micturition. Also, it increases atrioventricular nodal conduction and thus may increase ventricular rate in patients with AF. It is important to realize that although medications may ameliorate symptoms, drug therapy does not appear to decrease the probability of sudden death. In a recent study of 173 patients who were taking amiodarone, β-blockers, verapamil, and/or sotalol for treatment of symptoms, there was no difference in sudden death mortality compared with patients who were on no pharmacologic therapy.[15] Thus, ICDs remain the primary therapy used for prevention of sudden death in high-risk HOCM patients.

### Technique of Operation

Operation is performed through a median sternotomy, and normothermic cardiopulmonary bypass is established in the standard fashion using a single, two-staged venous cannula. The aorta is cross-clamped, and cold blood cardioplegia (1000–1200 mL) is infused through the aortic needle vent to arrest the heart. Adequate exposure of the subaortic septum is critically important, and several maneuvers facilitate the operation. First, pericardial sutures are used only on the right side to elevate the pericardium toward the surgeon. Next, an oblique aortotomy is made slightly closer to the sinotubular ridge than is usual for aortic valve replacement, and the incision is carried through the midpoint of the noncoronary aortic sinus of Valsalva to a level approximately 1 cm above the valve annulus. The edge of the proximal aorta is held out of the way with small stay sutures, and a cardiotomy sucker is placed through the aortic valve and used to depress the anterior leaflet of the mitral valve and protect it from injury. The right aortic valve cusp is collapsed against the sinus wall where it will usually stay. A sponge stick is used to depress the right ventricle and rotate the septum posteriorly, orienting the LV outflow anteriorly.

A standard No. 10 scalpel blade is used for myectomy; incision in the septum begins just to the right of the nadir of the right aortic sinus (Fig. 46-4). The incision in the septum is made upward and then leftward over to the anterior leaflet of the mitral valve. Scissors are used to complete excision of this initial portion of the myocardium. The area of septal excision is then deepened and lengthened toward the apex of the heart being certain to excise hypertrophied septum beyond the endocardial scar. Trabeculations are excised, and the myectomy site is further enlarged with the use of pituitary rongeurs. Adequate septal myectomy usually yields 3 to 12 g of muscle. Use of the sponge stick to depress the heart posteriorly will improve exposure of the distal extent of the myectomy. The aortotomy is closed and the operation proceeds as usual.

This technique for a more extended myectomy[16] differs from the standard Morrow operation in which parallel incisions create a trough in the septum that extends up to 3 cm from the aortic valve; wider excision of muscle in the immediate subaortic area improves exposure of the distal extent of

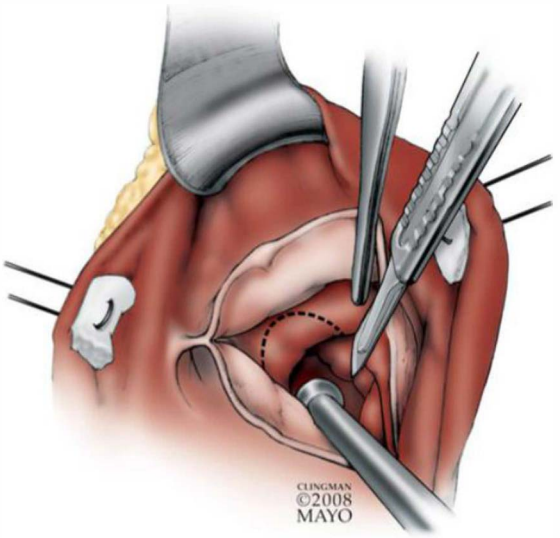

**FIGURE 46-4** Septal excision begins just to the right of the nadir of the right aortic sinus and extends leftward toward the anterior leaflet of the mitral valve. After the initial specimen is removed, the area of septal excision should be carried toward the apex of the heart well past the endocardial scar. A wider proximal area of excision improves exposure of the more distal extent of septectomy. (By permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

the hypertrophied septum, and excision extends up to 7 cm from the aortic valve. Inadequate myectomy results more often from failure to excise sufficient length of the septum (toward the apex) than from inadequate depth of excision. Importantly, the methods described above have proved adequate for all patients with subaortic obstruction, and maneuvers such as anterior leaflet plication are unnecessary and potentially harmful. Mitral valve replacement is reserved for patients with intrinsic leaflet abnormalities that cannot be repaired. To confirm complete relief of the LVOTO, we routinely measure simultaneous aortic and LV pressure by direct needle puncture before and after myectomy. If the resting LVOT gradient is diminished by the effects of anesthesia, premature ventricular beats are induced by stimulating the ventricle to elicit the dynamic gradient produced by the Brockenborough phenomenon; the postextrasystolic contraction is more forceful due to increased contractility and decreased afterload. The same maneuver is then repeated after myectomy. Intraoperative TEE can identify residual MR, SAM, and any septal defects created by excision of septal muscle.

Unroofing of coronary artery bridging is performed in selected cases, particularly young patients and those who have angina preoperatively. After identification of the coronary artery distal to the intramyocardial segment, the anterior surface of the vessel is exposed by sharp dissection that is continued proximally until the LAD reemerges onto the epicardium. The divided myocardium over the artery is usually 3 to 5 mm thick. If the course of the artery is so deep that trabeculations of the right ventricular cavity are entered, pledgeted sutures placed deep to the coronary artery can repair the opening into the ventricle.

# OUTCOMES

## Early Results

### MORTALITY

Risk of hospital death after isolated septal myectomy for HOCM is low, generally less than 1 percent in experienced centers (Fig. 46-5). Surgical risk may be higher among very elderly patients (particularly those with severe disabling symptoms associated with pulmonary hypertension), patients with prior myectomy, or those requiring concomitant procedures.

### MORBIDITY

Complications such as complete heart block requiring permanent pacemaker and iatrogenic ventricular septal perforation have become uncommon (≤1–2 percent). Partial or complete left bundle branch block is a frequent finding after surgical myectomy but is not associated with adverse

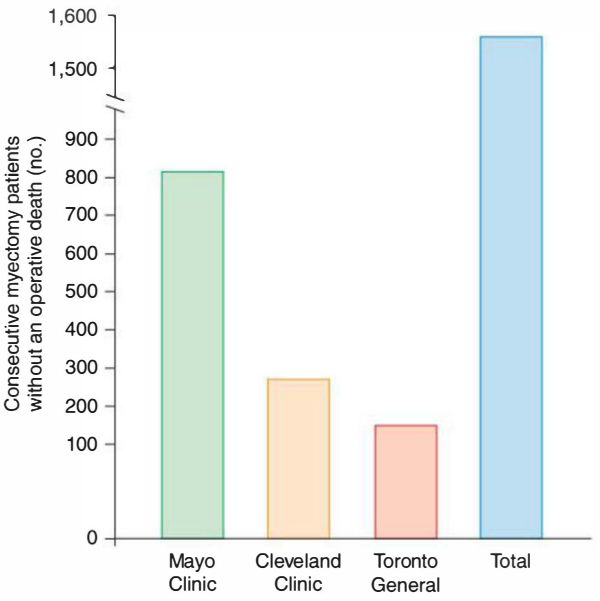

**FIGURE 46-5** Operative risk of isolated septal myectomy for hypertrophic cardiomyopathy is less than 1 percent and approaches zero in centers with broad experience with the procedure. (Reproduced with permission from Maron BJ. Surgical myectomy remains the primary treatment option for severely symptomatic patients with obstructive hypertrophic cardiomyopathy. *Circulation* 2007;116:196–206. Copyright Wolters Kluwer Health.)

sequelae. However, if the patient has complete right bundle branch block preoperatively, interruption of the left bundle after myectomy increases risk of complete heart block. This is particularly important in patients who have had alcohol septal ablation prior to operation. Elbardissi et al. reported that the risk of postoperative pacemaker insertion was 36 percent in patients who underwent alcohol septal ablation before myectomy compared with 3 percent for those without prior intervention.[17]

## Late Results

### SYMPTOM RELIEF

Improvement in symptoms and exercise capacity after myectomy is highly predictable and durable; over 90 percent of severely symptomatic patients have improvement of ≥ two function classes. Indeed, relief of outflow gradients by myectomy is equally effective in improving limitation due to dyspnea, angina, or syncope. Importantly, symptomatic benefit of myectomy is directly related to reducing the basal outflow gradient and MR and restoring normal LV systolic and end-diastolic pressures (in more than 90 percent of patients) which, in turn, may also favorably influence LV diastolic filling and myocardial ischemia. Relief of the gradient may decrease left atrial size and the subsequent risk of developing AF.

Late recurrence of large resting LV outflow gradients is very uncommon after successful myectomy in either adults or children with HOCM; this is in contrast to patients who have surgery for relief of congenital membranous subaortic stenosis. The most common causes of recurrent symptoms and obstruction are limited myectomy at the initial operation, mid-ventricular obstruction, and anomalies of papillary muscles. Most often, inadequate myectomy at initial operation is due to failure to extend the myectomy far enough toward the apex of the heart.[18]

## SURVIVAL

Septal myectomy is usually performed for relief of symptoms, but there is evidence that operation may improve survival of patients with HOCM. In the report of Ommen et al., late survival of 289 patients with HOCM undergoing septal myectomy was 98, 96, and 83 percent 1, 5, and 10 years postoperatively, and this survival was similar to that of an age- and sex-matched US population and similar to survival of HCM patients without obstruction (Fig. 46-6). In the same study, myectomy patients had superior survival free from all-cause mortality ($P < 0.001$), HCM-related mortality ($P < 0.001$), and SCD ($P = 0.003$) compared with unoperated HCM patients with obstruction (Fig. 46-7). On multivariable analysis, performance of myectomy had a strong, independent association with survival (hazard ratio 0.43; $P < 0.001$).

Recent studies also suggest mechanisms whereby relief of LVOT gradients might improve survival. The extent of

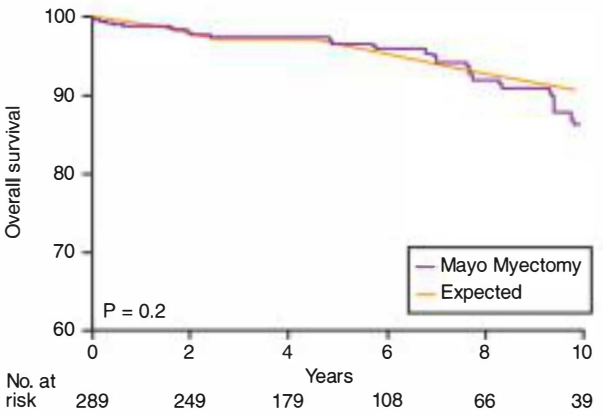

**FIGURE 46-6** Survival of patients with hypertrophic obstructive cardiomyopathy after septal myectomy is similar to and age and gender matched population. (Reproduced with permission from Ommen SR, Maron BJ, Olivotto I, et al. Long-term effects of surgical septal myectomy on survival in patients with obstructive hypertrophic cardiomyopathy. *J Am Coll Cardiol* 2005;46:470–476. Copyright Elsevier.)

LV hypertrophy is an important determinant of survival in patients with HCM, and successful myectomy results in some regression of LV hypertrophy.[19,20] Thus, patients with the obstructive form of HCM may have an additive burden of ventricular hypertrophy caused by pressure overload that is relieved by successful myectomy. Although the severity of LVH is a determinate of survival in unoperated patients, left ventricular mass and wall thickness are not predictors of late survival in HCM patients following myectomy.[21]

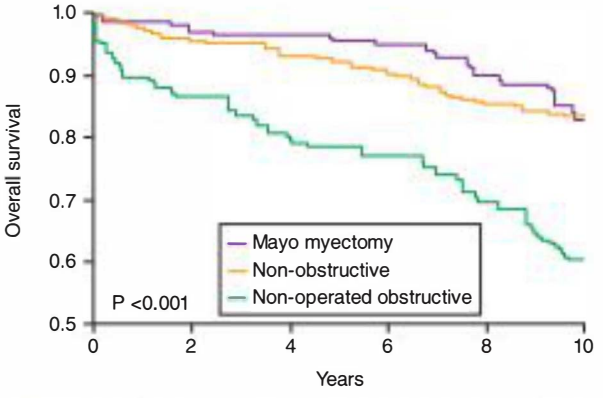

**FIGURE 46-7** Survival free from all-cause mortality in three hypertrophic cardiomyopathy patient subgroups: Mayo Clinic surgical myectomy ($n = 289$), non-operated with obstruction ($n = 228$), and non-obstructive ($n = 820$). Myectomy vs non-operated obstructive hypertrophic cardiomyopathy, $P < 0.001$; myectomy vs non-obstructive hypertrophic cardiomyopathy, $P = 0.8$. (Reproduced with permission from Ommen SR, Maron BJ, Olivotto I, et al. Long-term effects of surgical septal myectomy on survival in patients with obstructive hypertrophic cardiomyopathy. *J Am Coll Cardiol* 2005;46:470–476. Copyright Elsevier.)

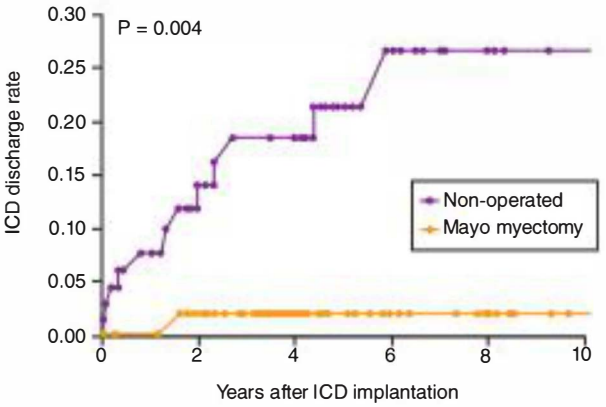

**FIGURE 46-8** Implantable cardioverter defibrillator discharge rates among patients with HCM who had septal myectomy compared with non-myectomy patients. Average annualized implantable cardioverter defibrillator discharge rates of 0.24 percent in the myectomy group, compared with 4.3 percent in the non-myectomy group ($P = 0.004$). (Reproduced with permission from McLeod CJ, Ommen SR, Ackerman MJ, et al. Surgical septal myectomy decreases the risk for appropriate implantable cardioverter defibrillator discharge in obstructive hypertrophic cardiomyopathy. *Eur Heart J* 2007;28:2583–2588. Copyright Oxford University Press.)

Additional insights on improved survival of myectomy patients come from McLeod and associates who reviewed patients with HCM who had received ICDs.[22] During follow-up (median 4.5 years), 12 patients (17 percent) in the non-myectomy group and only 1 patient (2 percent) in the myectomy group had appropriate ICD discharges (Fig. 46-8). The average annualized event rate was 4.3 percent/year in the non-myectomy group, compared with 0.24 percent/year following myectomy ($P = 0.004$). Thus, surgical myectomy and relief of outflow gradient are associated with a marked reduction in the incidence of appropriate ICD discharges and risk of SCD.

## COMPARISON TO SEPTAL ARTERY ABLATION

Septal reduction can be achieved by selective infarction of septal branches of the LAD, and the advantages of avoiding surgical incision and hospitalization are obvious. In a review of alcohol septal ablation from 42 published studies (2959 patients), resting LVOT gradient decreased from 65 to 16 mm Hg ($P < 0.001$), basal septal diameter reduced from 21 to 14 mm ($P < 0.001$), and hospital mortality was 1.5 percent.[23] However, the incidence of complete heart block requiring permanent pacemaker was 11 percent, and other important complications included coronary dissection (1.8 percent), pericardial effusion (0.6 percent), ventricular fibrillation (2.2 percent), stroke (1.1 percent), new right bundle branch block (46 percent), and new left bundle branch block (6.5 percent). Also, symptoms persisted in 11 percent of patients, redo alcohol ablation was required in 6.6 percent, and surgical myectomy was necessary in 2.0 percent. Thus, while this procedure is less invasive, it is not without significant morbidity and mortality.

Not all patients with HOCM are candidates for alcohol septal ablation because of unfavorable coronary anatomy. Also, concern has been raised about the potential long-term risk of sudden death related to arrhythmogenic substrate from the resulting septal scar. Cardiac magnetic resonance imaging demonstrates that, in most patients, alcohol septal ablation causes transmural tissue necrosis, located more inferiorly in the basal septum than myectomy; the infarct usually extends into the right ventricular side of the septum and sometimes spares the basal septum leading to residual gradients at follow-up. Thus, alcohol septal ablation is an option for patients who may have increased risk for operation, but septal myectomy remains the gold standard for patients with HCM and severe LV outflow obstruction who are refractory to maximal medical therapy.

## ROLE OF SURGERY IN MANAGEMENT OF HYPERTROPHIC CARDIOMYOPATHY BOARD REVIEW QUESTIONS (CHAPTER 46)

1. Which of the following is *not* true regarding morphology of HCM?
   A. The phenotype closely correlates with the genotype.
   B. Up to 20 percent of patients will have anomalies of the papillary muscles.
   C. Coronary flow reserve is reduced.
   D. CAD is present in 5 to 15 percent of patients.
   E. LAD muscular bridging is found in 15 percent.

2. Which of the following histopathologic and genetic findings is true in patients with HCM?
   A. The myocardial fibers are hypertrophied and arranged in parallel sheets.
   B. There is organized whirling of the fibers.
   C. Most cases are not familial.
   D. It is a genetically diverse disease.
   E. All family members should undergo genetic testing.

3. HCM results in:
   A. Systolic dysfunction
   B. LVOTO
   C. Functional mitral stenosis
   D. Asymmetric left ventricular free wall thickening
   E. Central mitral insufficiency due to SAM

4. Surgical repair of HCM may include all of the following *except*:
   A. Septal myectomy
   B. Incision of the ventricular wall below the commissure between the left and right coronary cusps
   C. Mitral valve replacement
   D. Unroofing of the LAD
   E. Extension of the ventricular incision toward the apex

5. Results after surgery for HCM include?
   A. Operative mortality of 5 percent
   B. Heart block and pacemaker incidence of 5 percent
   C. Relief of symptoms in over 90 percent of patients
   D. Long-term survival below the general population
   E. Higher incidence of new bundle branch block compared with septal alcohol ablation

## ANSWERS

1. **Answer: A.** The phenotype of HCM is not closely associated with the genotype, and there is widely variable expression.
2. **Answer: D.** HCM is genetically diverse, even within close family members. The histopathology is characterized by disorganization of the muscle fibers.
3. **Answer: B.** The asymmetric septal wall thickening results in left ventricular outflow tract obstruction. There is associated diastolic dysfunction and asymmetric mitral insufficiency due to SAM.
4. **Answer: B.** The incision for the septal myectomy begins just below the nadir of the right coronary cusp, not at the commissure. Mitral valve replacement and unroofing of muscular bridging of the LAD may also be required.
5. **Answer: C.** The vast majority of patients have relief of symptoms after surgery and enjoy survival equivalent to the general population. Both operative mortality and pacemaker requirement are less than 5 percent. There is a higher incidence of new bundle branch block after alcohol ablation.

# Pericardial Disease

*Eric J. Okum*
*Abe DeAnda Jr.*

## KEY CONCEPTS

- Epidemiology
  - Pericarditis and pericardial effusions have many etiologies, including inflammation, infection, immunologic disorders, malignancy, myxedema, uremia, pregnancy, aortic dissection, cardiac rupture, trauma, myocardial infarction, cirrhosis, and heart failure. The three most common etiologies are neoplasia, uremia, and idiopathic causes. Cardiac tamponade usually is caused by bleeding, followed by other sources of chronic effusions.
- Pathophysiology
  - The pathophysiology of pericardial inflammation relates to the underlying causes of pericardial effusions and pericarditis. Effusions generally arise when pericardial fluid production exceeds reabsorption. With pericardial tamponade, there is a rapid increase in intrapericardial pressure and diminished diastolic compliance, ultimately resulting in equalization of right and left atrial, right and left ventricular, pulmonary artery wedge, and intrapericardial pressures. Pericarditis arises from inflammation of the pericardial sac. In constrictive pericarditis, there is a limitation in cardiac filling that is reflected in a "square root" sign seen in ventricular pressure tracings during cardiac catheterization.
- Clinical features
  - The symptoms of pericardial effusions include dyspnea, fever, and chest pain, although many effusions are asymptomatic. The signs include a pericardial friction rub, global electrocardiogram (ECG) changes, and pulsus paradoxus. Cardiac tamponade presents as hypotension and decreased cardiac output; Beck's triad includes muffled heart sounds, elevated venous pressure, and decreased systemic arterial pressure. Significant constrictive pericarditis manifests with symptoms of right-sided heart failure, including jugular venous distention, worsening peripheral edema, and pleural effusions.
- Diagnostics
  - Echocardiography is the gold standard for the diagnosis of pericardial effusions. Cardiac tamponade is a clinical diagnosis but can be confirmed or substantiated with echocardiography. Computed tomography is useful in identifying the thickened pericardial sac in patients with pericarditis, although magnetic resonance imaging is more sensitive and specific in diagnosing constrictive pericarditis. Right and left cardiac catheterization is the gold standard for diagnosing constrictive pericarditis.
- Treatment
  - Pericardial effusions are treated most readily with drainage, pericardiocentesis, or a pericardial window. Adjunctive medical therapy can be successful, depending on the etiology of the effusion. Depending on the etiology, tamponade can be treated with pericardiocentesis, a pericardial window, or surgical (re)exploration. Medical treatment of constrictive pericarditis is predicated on treating the underlying cause; however, the mainstay of therapy is pericardiectomy.
- Outcomes and prognosis
  - The outcomes and prognoses for pericardial effusions and tamponade depend on the etiology. Early mortality for pericardiectomy ranges from 5 to 10 percent, with 5-year survival ranging from 65 to 90 percent. Predictors of poor outcome are prior radiation, renal insufficiency, poor ventricular function, pulmonary hypertension, New York Heart Association functional class IV, hyponatremia, ascites, and hyperbilirubinemia.

# INTRODUCTION

## Historical Highlights

Galen was the first to describe pericardial disease in animals (circa 160 AD) and subsequently described in two patients the surgical drainage of purulent pericardial effusions.[1] This predated Lower's 1669 description of pericarditis in humans.[2] There are apocryphal references of penetrating heart wounds being treated, usually by the removal of the offending object, without much information about how subsequent drainage of the pericardial space was dealt with. Francisco Romero, a Catalonian physician, was probably the first heart surgeon, earning this title when he performed open drainage of a pericardial effusion in 1801. He presented this work 15 years later, but it was silenced for being too aggressive.[3] This predates the "birth of heart surgery" by almost 100 years, when Rehn first successfully sutured a heart wound in 1896.[4]

In 1929, Beck showed experimentally that constrictive pericarditis could be produced and treated surgically in laboratory animals[5,6] using Dakin's solution. His observations of the extent of the adhesions formed (and the concomitant neovascular supply) probably contributed to his later procedures for ischemic heart disease.[7] Pericardiectomy was then translated to clinical practice. By 1941, Blalock reported a series of 28 patients[8] who had undergone this procedure.

This chapter focuses on many aspects of pericardial disease including cardiac tamponade, pericardial effusion, and pericarditis, with an emphasis on the surgical aspects of this disease.

## Anatomy

The pericardium is a conical sac that encloses the heart and great vessels. It is located posterior to the body of the sternum, bounded by the second and sixth costal cartilages anteriorly and thoracic vertebrae 5 to 8 posteriorly. The ascending aorta, pulmonary artery, and the superior vena cava exit from the cephalad opening of the pericardium. The base is fused with the central tendon of the diaphragm. Loose connective tissue called the sternopericardial ligaments attaches the anterior surface of the pericardium to the posterior table of the sternum.

The pericardium is composed of an outer and inner membrane. A thick layer termed the fibrous pericardium is external, while a thin transparent membrane called the serous pericardium is internal. The serous pericardium is further divided into parietal and visceral layers. The former is fused to the fibrous portion, while the latter is reflected onto the epicardium. The visceral layer of the serous pericardium is in fact the epicardium of the heart, and thus is also in continuity with the adventitia of the coronary vessels. The thin layer of fluid between the two layers allows the heart to move in a near-frictionless environment.

By virtue of the anatomic reflection of the pericardium, two sinuses exist—the transverse and the oblique pericardial

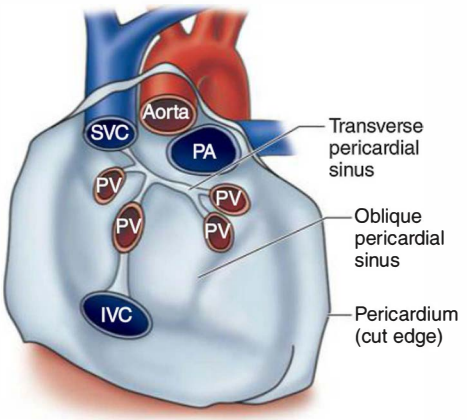

**FIGURE 47-1** Pericardial attachments and reflections. PA, pulmonary artery; PV, pulmonary vein; IVC, inferior vena cava; SVC, superior vena cava. (Reproduced with permission from Mangi AA, Torchiana DF. Pericardial disease. In: Cohn LH, Edmunds LH Jr (eds). *Cardiac Surgery in the Adult 2/3.* New York, NY: McGraw-Hill Publishers, 2003:1359–1372.)

sinuses (Fig. 47-1). The transverse sinus is located behind the ascending aorta and pulmonary trunk. If the pericardium is opened anteriorly, one can place a finger easily into this space and go from right lateral to left lateral pericardium. The larger sinus is the oblique sinus, which cradles the heart. One can see this space when the heart is lifted toward the right shoulder. This is a blind cul-de-sac, bordered to the right by the inferior vena cava (IVC). This therefore prevents passage around the IVC without sharp dissection. The two sinuses lie in near continuity with only a thin layer of serous pericardium separating the two.

The arterial supply of the pericardium comes mainly from the internal thoracic arteries. Smaller branches of the bronchial, esophageal, and superior phrenic arteries also contribute to the blood supply. The visceral layer of the serous pericardium is supplied by the coronary arteries. Venous drainage flows into the internal thoracic veins and azygous system. Nervous supply comes from the vagus, phrenic, and sympathetic trunks.[9]

## Embryology

The pericardium is derived, beginning the third week of gestation, from the progressive invagination of the intraembryonic coelomic cavity. This results in a creation of the visceral and parietal layers of the serous membrane, which will later become the serous pericardium. By the fourth week, with growth of the lung buds, pleuropericardial membranes are developed on each side. With continued growth and eventual fusion of the pleuropericardial membranes, the thoracic cavity becomes separated into the pericardial and two pleural cavities. This membrane will become the fibrous

pericardium. It is the failure of these membranes to fuse which results in congenital defects of the pericardium.[10]

## PERICARDIAL EFFUSION

### Epidemiology

The finding of a pericardial effusion is common in modern day cardiology and cardiothoracic surgical practices. The evolution and prevalence of noninvasive technology [i.e., echocardiography (ECHO)] has made the diagnosis of pericardial effusion both easier and apparently more frequent. Such incidental effusions are often discovered while patients are being evaluated for cardiac valvular disease. But many systemic processes other than cardiac can contribute to the development of pericardial effusions. All types of pericarditis (discussed later in this chapter) can lead to the development of effusions. Etiologies of pericarditis include infection, inflammation, immunologic disorders, malignancy, myxedema, uremia, pregnancy, aortic dissection, cardiac rupture, trauma, chylopericardium, postmyocardial infarction, cirrhosis, heart failure, and idiopathic.[11] Tuberculosis now is an uncommon cause of pericardial effusion but once was one of the more frequent etiologies of infective pericarditis. The clinical constellation of hemodynamic compromise, cardiomegaly, pleural effusion and large pericardial effusion were more common in those with tuberculosis than either malignancy or idiopathic causes.[12]

Multiple studies have shown the three most common etiologies for pericardial effusion to be neoplasia, uremia, and idiopathic.[13–15] Approximately 40 percent of these patients present with cardiac tamponade (discussed later).

### Pathophysiology

The pathophysiology of pericardial effusion relates to the underlying cause. As described above, fluid naturally exists between the two layers of the serous pericardium. It is when this fluid accumulates in the pericardial space that the pericardial effusion can become pathologic. The production of fluid is balanced by the corresponding absorption of fluid by lymphatic channels. The parietal pericardium is drained by the anterior and posterior mediastinal lymph nodes; visceral pericardium is drained via the tracheal and bronchial lymph nodes.[16] Pericardial mesothelial cells contain dense microvilli that facilitate ion and fluid exchange.[17] Effusions arise when production exceeds reabsorption. Thus, effusions can arise from either overproduction or from underabsorption.

### Clinical Features

A wide spectrum of clinical presentations exists for pericardial effusions. Many are asymptomatic and found incidentally by ECHO, this is especially true for elderly women.[18] On the other end of the spectrum are those patients presenting in cardiac tamponade.

Symptoms of pericardial effusions may include dyspnea, fever, chest pain, or hemodynamic instability. Signs include a pericardial friction rub, EKG abnormalities, or pulsus paradoxus (described in cardiac tamponade section).

Posner et al. found that the initial presentation of cardiac tamponade was suggestive of malignancy, especially with very large effusions. Fever, pericardial friction rub, and improvement after starting nonsteroidal anti-inflammatory drugs are suggestive of idiopathic pericardial effusion.[19] In 60 percent of patients, a known previous condition that could cause a pericardial effusion was present. The underlying condition was the cause in greater than 90 percent of these patients. The presence of inflammatory signs (chest pain, pericardial friction rub, fever, or EKG changes) was predictive for acute idiopathic pericarditis. Furthermore, a large effusion without tamponade or inflammatory signs was predictive of chronic idiopathic effusion. Tamponade without inflammatory signs was predictive of malignancy.[20]

### Diagnostic Modalities

Before the advent of ECHO, the diagnosis of a hemodynamically significant pericardial effusion was difficult and needed to be confirmed by physical exam. ECHO is now considered the gold standard for diagnosis of effusions (Fig. 47-2) and can help confirm the diagnosis of a hemodynamically significant effusion (tamponade). Importantly, a "negative" ECHO does not eliminate the possibility of tamponade. Cardiac catheterization can aid in the diagnosis of tamponade or pericardial constrictive disease, but does not impact the diagnosis of effusion.

Attention must be drawn to specific ECHO findings. Some patients with evidence of right atrial and ventricular collapse have no clinical evidence of tamponade. Levine et al.[21]

**FIGURE 47-2** Large pericardial effusion detected on echocardiogram. Note the large nonechogenic (dark) fluid-filled space around the entire heart.

performed right-sided heart catheterization and pericardiocentesis on a group of patients with ECHO evidence of tamponade. Many patients had no hemodynamic evidence of tamponade. Systolic blood pressure was greater than 100 mm Hg in 94 percent. Pulsus paradoxus was present in only one-third of patients. Right atrial collapse had a positive predictive value of only 50 percent.

## Treatment

### MEDICAL THERAPY

The success of medical therapy for pericardial effusions depends on the underlying disease processes that cause the effusion to occur. If systemic signs of inflammation are present, a course of nonsteroidal anti-inflammatory agents or steroids should be started, unless evidence of hemodynamic compromise is suspected. Any underlying infection should be treated if known.

Medical therapy is most useful with malignant effusions. Chemotherapy or radiotherapy may be useful in preventing recurrence after aspiration of the fluid. Vaitkus et al. report a success rate of 78 percent in preventing recurrence after systemic chemotherapy was given. Radiation therapy also had good results, especially with radiosensitive tumors such as lymphoma, with success rates greater than 90 percent. Instillation of sclerosing agents (e.g., tetracycline or bleomycin) through an indwelling catheter also reduced recurrence in some small series.[22]

### SURGICAL THERAPY

Surgical therapy of pericardial effusion consists of pericardiocentesis with or without catheter placement, pericardial window, and pericardiectomy. The indications and techniques will be described.

Pericardiocentesis or other modes of surgical drainage are indicated for patients with clinical aspects of cardiac tamponade, suspicion of infection, and in patients with large idiopathic chronic pleural effusions. Pericardiocentesis or drainage is not warranted in the initial management of asymptomatic patients with a large effusion. However, when large asymptomatic effusions persist for more than 3 months, the risk of tamponade without a specific inciting event approaches 30 percent.[23]

Pericardiocentesis can be performed either in the catheterization laboratory (under fluoroscopic guidance) or at the bedside. It should be the initial therapy for those in overt tamponade when such a procedure can be easily and safely performed, and for those patients that are not in the immediate postoperative period. Once the decision is made to proceed with pericardiocentesis, the decision is to perform either simple aspiration or percutaneous catheter drainage. These authors favor the latter approach. With this approach, the subxiphoid area is infiltrated with 1 percent lidocaine for local anesthesia. An 18-gauge spinal needle is inserted to the left of the xiphoid process at a 45° angle toward the left shoulder. A "pop" is felt when the needle enters the pericardial sac. This can be aided with either fluoroscopic or ECHO guidance. An 8F pigtail catheter is then placed in the pericardial space using the Seldinger technique. Fluid should be aspirated and then sent for culture and cytology. If blood is withdrawn, it is placed in a small basin and observed. Clotted blood suggests that a cardiac chamber was entered. If ECHO is being used for guidance, a simple bubble study can be used to verify extracardiac positioning of the catheter needle. A follow-up CXR evaluates catheter placement and any evidence of pneumothorax. Techniques have also been described using an alligator clip attached to the needle and one lead of the EKG. When the myocardium is violated with the needle, a deflection will be noted on the EKG.

Pericardial drainage can also be achieved by creating a pericardial window. Surgical approaches include subxiphoid, left anterior thoracotomy, or thoracoscopy (VATS). General anesthesia is preferred for all approaches. Especially when tamponade is the presumptive diagnosis, the patient should be prepped and draped prior to induction of anesthesia since hypotension and hemodynamic instability may ensue, and rapid drainage may be necessary.

The subxiphoid approach consists of a 6- to 8-cm incision that starts at the junction of the sternum and xiphoid. The xiphoid process is either resected or split. An Army–Navy retractor is placed under the sternum. Dissection is continued under the sternum until the pericardium is identified and incised. The fluid is drained and sent for culture and cytology. The largest possible piece of pericardium is resected and any intrapericardial loculations are broken with finger dissection. A 28F right-angled chest tube is placed into the pericardial space through a separate stab incision. The surgical pericardial incision can be closed, left opened, or drained into the peritoneal space.

Pericardial drainage can be approached by left anterior thoracotomy. A double-lumen tube is not necessary for this approach. A small roll should be placed under the patient's left shoulder, so that the patient is at a 30° angle from the table. A 6- to 8-cm incision is made in the infra-mammary crease with the nipple as its most medial aspect. Subcutaneous dissection is continued superiorly for one rib space. The fourth intercostal space is entered; the intercostal muscles are taken off the fifth rib medially and laterally. A sponge stick is used to push the lung away. The pericardium is identified and incised. The fluid is drained and sent for culture and cytology. The pericardium is resected anterior to the phrenic nerve, with the largest possible section being taken. The incision is closed after a 28F chest tube is placed through a separate stab incision. The pericardial space can be drained directly with the chest tube, or the tube can be left in the pleural space under the assumption that any reaccumulation of pericardial fluid will drain into the pleural space.

Thoracoscopy can be used to create a pericardial window. However, this approach does require placement of a dual lumen endotracheal tube and single lung ventilation. Patients with clinical tamponade often will not tolerate this approach.

A port for the camera and two working ports are placed. The chest cavity is first inspected, including identification of the phrenic nerve. The pericardium is then incised anterior to the nerve and a large piece of pericardium is resected. Care is taken not to leave a defect so large that cardiac herniation may occur. A single 28F chest tube is left in the pleural space.

## Outcomes/Prognosis

The outcomes and prognoses for pericardial effusions relate to the underlying disease process. Patients with malignant effusions have a median survival of 2 to 3 months.[24] A recent study by McDonald et al.[25] compared subxiphoid pericardial window to percutaneous catheter placement. No direct procedural mortality occurred in either group. However, the in-hospital mortality and recurrence rates were significantly higher in the percutaneous group. Allen et al. reviewed combined results in the literature, and similar results were noted.[26] Surgical drainage had mortality, complication, and recurrence rates of 0.6, 1.5, and 3.2 percent, respectively. Catheter drainage had rates of 1.9, 10.6, and 13.8 percent, respectively. Thus, despite the relatively short-term benefit of any procedure, compared with percutaneous approaches, surgical drainage may allow more patients to be discharged from the hospital.

# CARDIAC TAMPONADE

## Epidemiology

Cardiac tamponade occurs when the increase in pericardial fluid leads to a significant rise in intrapericardial pressure, subsequently causing hemodynamic embarrassment. Etiologies include bleeding (spontaneous, traumatic, postoperative) and other sources of chronic effusions (discussed previously).

Cardiac surgeons are most familiar with cardiac tamponade in the immediate postoperative period. Series report that the overall incidence is 0 to 8 percent[27,28] following cardiac surgery. Tamponade in the postoperative period can be difficult to diagnose since typical signs and symptoms may be related to expected (or assumed) cardiac dysfunction (e.g., low output syndrome). Because of this, tamponade is a diagnosis of exclusion, but one that must be entertained early in the postoperative period for the unstable patient.

## Pathophysiology

Under normal circumstances, intrapericardial pressure is similar to intrapleural pressure, both being subatmospheric. As left ventricular volume increases by rapid infusion of blood during early diastole, intrapericardial pressure increases. Understandably, during this time the right ventricle is also filling. Since the right ventricle is thin walled, however, increases in intrapericardial pressure (or extrinsic compression from a clot) can exert a more deleterious effect upon this chamber. With tamponade, accumulation of fluid in the relatively non-compliant pericardial space (tough fibrous pericardium) causes the intrapericardial pressure to increase rapidly,. Additional increases in intrapericardial fluid result in the loss of diastolic compliance and depressed cardiac function.

As the consequences of tamponade progress, higher filling pressures are required for the ventricles to fill. Compensatory mechanisms include higher systemic and pulmonary artery pressures by vasoconstriction,[29] tachycardia, time-dependent pericardial stretch, and blood volume expansion.[30] This latter mechanism only aids in compensating for slow-growing pericardial effusions.

Intrapericardial pressure rises initially to levels greater than left and right atrial pressures with the aforementioned compensatory mechanisms occurring. When right and left atrial, right and left ventricular, pulmonary artery wedge, and intrapericardial pressures equalize, cardiovascular collapse ensues.

## Clinical Features

Cardiac tamponade presents as hypotension and/or decreased cardiac output. Venous pressures are elevated, and jugular venous distension may be present. The classic Beck's triad,[31] muffled heart sounds, elevated venous pressure, and decreased systemic arterial pressure, may or may not be present.

The cardiac surgeon encounters cardiac tamponade most often in the immediate postoperative period. Although the classic signs of tamponade (equalization of right and left heart pressures, decreased cardiac output, and hypotension) may be present, the clinical diagnosis is often more subtle. Other features can include decreased urine output, worsening acidosis, increased inotrope or pressor dependence, or new hemodynamic instability. These authors advocate prompt surgical reexploration if any of the above criteria are met and tamponade is plausible.

## Diagnostic Modalities

Physical examination may aid in making the diagnosis of cardiac tamponade. Beck's triad may be present. Jugular venous distension and pulsus paradoxus may also be present. Pulsus paradoxus is characterized by a decrease in systolic blood pressure by 10 mm Hg during quiet inspiration.[32] The mechanism results from increased caval blood flow during inspiration on the nonintubated patient. With increased venous return, right ventricular volume increases. Because of the increased pressure in the pericardial space, the septum is shifted and left ventricular volume is decreased. This translates into decreased cardiac output and arterial hypotension.

ECHO confirms the diagnosis and can confirm the size and extent of effusions. ECHO can confirm pulsus paradoxus when inspiration increases right ventricular size while decreasing left ventricular size in the presence of a large pericardial effusion. Compression of the right ventricular free wall during late diastole–early systole lasting more than one-third of the cardiac cycle is a sensitive sign. Right ventricular indentation during early diastole is more specific.[33] One must remember that tamponade is not an all-or-none phenomenon. The use of ECHO in the immediate postoperative period can be problematic. Transthoracic views can be limited by chest tubes or dressings. Immediately postoperatively, some degree of effusion always exists. Although ECHO may give you the diagnosis of tamponade, it does not rule out tamponade. We abide by the dictum that postoperative cardiac tamponade is a clinical, not echocardiographic, diagnosis.

## Treatment

### MEDICAL THERAPY

Very little medical therapy exists for cardiac tamponade. The mainstay consists of volume expansion to optimize preload while procedural intervention is planned.

### SURGICAL THERAPY

Surgical therapy for cardiac tamponade depends on the circumstances in which tamponade arises. The goal of surgical therapy is two-fold: relieve extrinsic cardiac compression and reverse the inciting event. Surgical therapy for pericardial effusions with tamponade physiology was discussed in the previous section.

In the postoperative period, sternal reentry is the approach of choice. Careful attention should be focused on the specific location of clot. For example, thrombus around the aorta should lead the surgeon to the aortic cannulation site or proximal anastomoses as potential sources for bleeding. Nevertheless, complete exploration and verification of all surgical sites is paramount. Aggressive correction of any coagulopathy should also occur; this includes ensuring that the patient is warm. All too often, we forget that a cause of coagulopathy is hypothermia. Rapid infusion of cold volume can exacerbate the problem.

Cardiac tamponade from trauma poses a more difficult problem. In this setting, the surgical approach is dictated by the mode of injury. Penetrating injuries should be explored according to the direction of trajectory. Pericardiocentesis may alleviate tamponade in the emergency room until an operating room is available. When we have planned an exploration via the left chest, we have occasionally started with a subxiphoid window to eliminate blood in the pericardium prior to placing the patient in the lateral decubitus position. Left thoracotomy, median sternotomy, and clamshell incisions all provide access to the pericardium and drainage of blood. Presence of other suspected injuries should dictate which approach is taken.

# PERICARDITIS

## Epidemiology

Over the last half of the century, etiologies for pericarditis have changed. Historically, tuberculosis (TB) was the major cause of infective pericarditis. Infectious diseases now cause fewer cases of pericarditis with the emergence of other etiologies such as previous cardiac surgery, malignancy, radiation, and trauma.[34]

Infection does remain a common cause of pericarditis. Sources include the heart itself, the surrounding tissues, septicemia, and from the incision in postoperative patients. Sources can be both bacterial and viral. As expected, infections are much more serious in immunosuppressed patients such as transplant and AIDS patients. Viral pericarditis is usually mild and self-limiting and may in fact be subclinical. On the other hand, acute bacterial pericarditis can be life threatening. The most common agents of bacterial pericarditis are streptococcus, pneumococcus, and staphylococcus.[35] Although now less common now, TB remains an etiology, especially in the immunocompromised patient. The pathologic stages seen in tubercular pericarditis are characterized by fibrinous exudation followed by serosanguinous effusions. These resorb and organize into caseating granulomas, pericardial thickening, fibrosis, and constriction.[36]

Pericarditis can be seen in renal failure patients, either due to infection (from dialysis access for example), their relative immunosuppressed state, or from uremia. Although the exact etiology of uremic pericarditis is unknown, nitrogen retention is required for its development. This condition was first described by Bright in 1836.[37]

A few drugs are classically associated with pericarditis. These are procainamide, hydralazine, methylsergide, emetine, and minoxadil.

Other metabolic causes of pericarditis include systemic lupus erythematosus (SLE), hypothyroidism, and rheumatoid arthritis (RA). Approximately one-half of patients with RA have pericardial effusions or pericardial adhesions. Patients with more severe RA tend to have worse pericardial issues, thought to be related to the deposition of immune complexes in the pericardium.[38]

Radiation is the most common cause of constrictive pericarditis in the United States,[39] and is dominant in part from an era when mediastinal irradiation was a common form of treatment for lymphoma. Postmastectomy irradiation as well as treatment of some lung cancers also contributes. The degree of inflammation and subsequent constriction relates to the total dose of radiation. One series reported that over 20 percent of patients with radiation-induced pericarditis ultimately require pericardiectomy.[40]

Trauma, cardiac surgery, and myocardial infarction account for additional causes of pericarditis. Both blunt and penetrating trauma can result in pericarditis as a sequelae to even a small, bloody pericardial effusion. Approximately 50 percent of patients that have had a transmural myocardial infarction develop pericarditis, known as Dressler's syndrome. Constrictive pericarditis can result from cardiac surgery, but this occurs in less than 5 percent of patients.[41]

## Pathophysiology

Pericarditis by definition is an inflammation of the pericardial sac. The degree as well as extent of inflammation will vary from patient to patient, as will the subsequent events following this inflammation. For pathological pericarditis (i.e., resulting in constrictive pericarditis) the basic premise is that inflammation leads to scar and fibrosis (Fig. 47-3). This, in turn, leads to constriction and the pathophysiologic processes described below.

The sine qua non of constrictive pericarditis is limitation in cardiac filling. The atria serve three functions: a conduit, a reservoir, and a pump. The primary function is that of a conduit and contributes to the rapid early filling of the ventricles during diastole. The majority of diastolic filling occurs in early diastole. This process of filling becomes abnormal when the distension of the ventricles is limited by the fibrous pericardium. Pressures within the heart chambers are relatively normal until the distention of the ventricles becomes limited. End diastolic pressures suddenly increase, manifested by the "square root" sign seen on ventricular pressure tracings during cardiac catheterization.

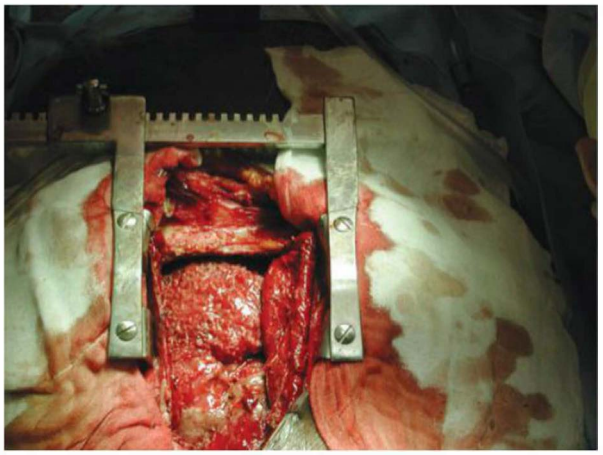

**FIGURE 47-3** Fibrinous pericarditis. Note the characteristically thickened walls of the opened pericardial sac and the intrapericardial adhesions. (Reproduced with permission from Abe DeAnda Jr., MD.)

## Clinical Features

Clinical findings depend on the severity of constriction. Patients with mild constriction may be asymptomatic. As constriction becomes more severe, signs and symptoms of heart failure become more pronounced; the heart failure may be limited to one side or biventricular. Venous pressures become higher and symptoms of right-sided heart failure become more prominent. Early symptoms include jugular venous distension, hepatomegaly, and peripheral edema. As symptoms progress, ascites, worsening peripheral edema, and pleural effusions may develop.

## Diagnostic Modalities

A few signs may be present with constrictive pericarditis. During inspiration, jugular venous distension may worsen; this is the so-called Kussmaul's sign. Pulsus paradoxus may also be present. A prominent S3 heart sound may be heard. This pericardial knock is secondary to the rapid ventricular filling during diastole. Murmurs are often absent.

Basic studies such as CXR and ECG may be useful in pointing the clinician to the diagnosis. Nonspecific ST elevation or T-wave abnormalities are present in more than 90 percent of patients. On CXR, pericardial calcification is seen in 40 percent of patients.[42] Computerized tomography (CT) can demonstrate a thickened pericardium (Fig. 47-4). Isolated findings must be supported by physiologic criteria. Another modality is MRI, which is more sensitive and specific than CT in the diagnosis of constrictive pericarditis. MRI can show right atrial dilatation and

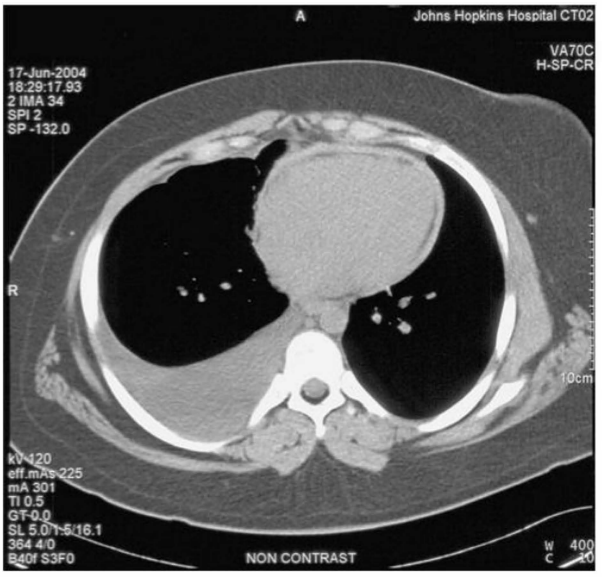

**FIGURE 47-4** Computed tomogram of revealing thickened pericardium consistent with constrictive pericarditis.

right ventricular compression. Pericardial thickness greater than 4 mm by MRI is suggestive of constriction in patients with appropriate clinical presentation. MRI can also show variations in respiratory-related filling, suggesting constriction.[43] The sensitivity and specificity of MRI is greater than 90 percent.[44]

ECHO can be useful in constrictive pericarditis. The initial role of 2-D ECHO can exclude other causes of right-sided heart failure. Pericardial thickening can be seen but is not diagnostic. Displacement of the interatrial septum toward the left atrium during inspiration and septal bounce are suggestive of pericardial constriction. M-mode Doppler can show signs of rapid early diastolic filling, ventricular interdependence, and increased right-sided diastolic pressure. All are signs of pericardial constriction.[45] Tissue Doppler imaging is a newer echocardiographic technique that can aid in making the diagnosis of constriction and has a high sensitivity (82.5 percent) and specificity (92.7 percent) in differentiating constrictive pericarditis from controls.[46]

Right and left heart cardiac catheterization remains the gold standard in the diagnosis of constrictive pericarditis. Hallmark features include equalization of end-diastolic pressures in the right atrium, left atrium, and pulmonary artery. Right and left ventricular pressures are also equalized.[47] Mean atrial pressures should be above 10 mm Hg on the right and left side of the heart. The "square root" sign, described earlier, is seen on ventricular tracing during catheterization (Fig. 47-5). The right atrial tracing demonstrates a prominent Y descent. The left ventricular ejection fraction should be greater than 40 percent. RVEDP is elevated and should be greater than one-third of RV systolic pressure. This finding has 95 percent sensitivity for the diagnosis of constrictive pericarditis.[48]

The clinician often has difficulty differentiating restrictive cardiomyopathy from constrictive pericarditis. Making the diagnosis is critical because constrictive pericarditis can be surgically cured. Transplantation is the only surgical treatment for restrictive cardiomyopathy. The above criteria are neither very sensitive nor specific to aid in making this distinction. Criteria suggestive of restrictive cardiomyopathy include the following: small- or normal-sized heart, reduced left ventricular function, pulmonary and hepatic congestion, and prominent X and Y descents on atrial tracing. Yet, none of these is pathognomonic.

Ventricular interdependence is the most sensitive and specific test for constrictive pericarditis. This is observed during cardiac catheterization. During the respiratory cycle, concordant increases in right and left ventricular pressure are expected with inspiration. With constrictive pericarditis, discordance is seen. This observation has a sensitivity of 100 percent and a specificity of 95 percent.[49]

When the diagnosis remains unclear after cardiac catheterization, more invasive means can be used to aid in making the diagnosis. Endomyocardial biopsy may be useful. If it is normal or there are mild inflammatory changes, biopsy does not help in distinguishing restrictive from constrictive pericarditis. Findings of amyloid are diagnostic for restrictive cardiomyopathy. Shoenfeld et al. found that the diagnosis of restrictive cardiomyopathy was made on biopsy in 39 percent of patients when the diagnosis was unclear after less invasive testing.[50]

When all other modes of testing fail, the diagnosis can be made by mini exploratory thoracotomy. If no pericardial pathology is present, the patient is closed. If constrictive pericarditis is found, formal pericardectomy is done.

## Therapy

### MEDICAL THERAPY

Treatment of the underlying cause of pericarditis is the only medical therapy. However, most often the etiology is unknown. Surgical therapy remains the mainstay of treatment.

### SURGICAL THERAPY

Once the diagnosis of constrictive pericarditis is confirmed, operative intervention is employed. Many patients present with advanced heart failure. An arterial line and pulmonary artery catheter should be placed. Surgical approaches include median sternotomy, left anterior thoracotomy, or bilateral anterior thoracotomies, and will vary based on surgeon preference and patient history.

The median sternotomy approach starts in the usual manner. The cardiopulmonary bypass pump should be set up and made ready. The thymic fat pad is dissected to the innominate vein. The anterior aspect of the pericardium is palpated and inspected. A scalpel is used to incise the pericardium in the midline, starting anterior to the aorta. Care must be taken during this step as the pericardium often is densely adherent to the heart. Pericardial flaps are lifted inferiorly and laterally. The dissection over the left side of the heart may need to be done on cardiopulmonary bypass. The pericardium needs to be stripped from phrenic nerve to phrenic nerve laterally,

the diaphragm inferiorly, and the atrioventricular groove superiorly. Bands between the right ventricle and the pulmonary artery need to be excised. Failure to do so may lead to pulmonary hypertension.[51] One may need to leave islands of unstripped pericardium over the coronaries, remembering that the serous visceral pericardium is in continuity with the adventitia of the coronary arteries. The pericardium over the right atrium and cavoatrial junction does not need to be stripped, as there is no hemodynamic advantage to this and the risk of bleeding is substantial.[52]

An alternative surgical approach for performing a pericardectomy is a left anterior thoracotomy. The patient is intubated with a dual-lumen endotrachial tube. An arterial line and pulmonary artery catheter is placed. The groins should be prepped should cardiopulmonary bypass be needed. A small roll is placed under the left shoulder. The lung is deflated and the fourth intercostal space is entered through a left inframammary incision. The phrenic nerve is identified\ and the pericardium is incised anteriorly. Dissection is continued anteriorly to the right atrium, inferiorly to the diaphragm, and superiorly to the pulmonary artery.

Sometimes the dissection of the right ventricle is very difficult through this incision. The left anterior thoracotomy can be extended across the sternum to a right anterior thoracotomy (clamshell incision). This exposure is outstanding. Only rarely is cardiopulmonary bypass needed with this approach. All surgical approaches offer equal results and should be dictated by surgeon preference.

## Outcomes/Prognosis

Early mortality for pericardiectomy ranges from 5 to 10 percent, with 5-year survival ranging between 65 and 90 percent. Patients with idiopathic cardiomyopathy had the best survival (88 percent 7-year survival). Predictors of poor outcome were prior radiation, renal insufficiency, poor ventricular function, higher pulmonary artery pressures, NYHA class IV, low serum sodium, ascites, and hyperbilirubinemia.[36,53,54]

## PERICARDIAL DISEASE BOARD REVIEW QUESTIONS (CHAPTER 47)

1. Beck's triad consists of muffled heart sounds, elevated venous pressure, and:

   A. Decreased systemic arterial pressure
   B. Friction rub
   C. Peripheral edema
   D. Fever
   E. Leukocytosis

2. The three most common etiologies for pericardial effusion include uremia, idiopathic, and:

   A. Tuberculosis
   B. Myocardial infarction
   C. Neoplasia
   D. Trauma
   E. Heart failure

3. Which modality is considered the gold standard for diagnosing pericardial effusions?

   A. Computed tomography
   B. Magnetic resonance imaging
   C. Cardiac catheterization
   D. Echocardiography
   E. Pulmonary arterial catheterization

4. Predictors of poor outcome after pericardiectomy include all but which of the following:

   A. Prior radiation
   B. Renal insufficiency
   C. Poor ventricular function
   D. NYHA class IV symptoms
   E. Hypernatremia

5. Hallmark features for constrictive pericarditis include all but which of the following:

   A. Equalization of end-diastolic pressures in the right atrium, left atrium, and aorta
   B. Equalization of right and left ventricular pressures
   C. "Square-root" sign on ventricular tracings during catheterization
   D. Elevated right ventricular end-diastolic pressure (RVEDP) that is greater than one-third of the right ventricular systolic pressure
   E. Equalization of end-diastolic pressures in the right atrium, left atrium, and pulmonary artery.

## ANSWERS

1. **Answer: A.** Beck's triad consists of muffled heart sounds, elevated venous pressure, and decreased systemic arterial pressure. Although a friction rub, peripheral edema, fever, and leukocytosis can be associated with pericarditis and/or a pericardial effusion, they are not components of Beck's triad.
2. **Answer: C.** The three most common etiologies for pericardial effusion include uremia, idiopathic, and neoplasia. Myocardial infarction, trauma, and heart failure are also etiologies for pericardial effusion, but not as common statistically. Tuberculosis is now an uncommon cause of pericardial effusion.
3. **Answer: D.** Echocardiography is considered the gold standard for diagnosing pericardial effusions. Although computed tomography, magnetic resonance imaging, cardiac catheterization, and pulmonary arterial

catheterization can also visualize and/or aid in the diagnosis of pericardial effusions, echocardiography does not use ionizing radiation and also demonstrates the functional manifestations of hemodynamically significant effusions (e.g., right ventricular chamber collapse).

4. **Answer: E.** Predictors of poor outcome after pericardiectomy include prior radiation, renal insufficiency, poor ventricular function, NYHA class IV symptoms, hyponatremia, ascites, and hyperbilirubinemia. Hypernatremia is not an identified predictor of poor outcome after pericardiectomy.
5. **Answer: A.** Hallmark features for constrictive pericarditis include equalization of end-diastolic pressures in the right atrium, left atrium, and pulmonary artery, equalization of right and left ventricular pressures, and the "square-root" sign on ventricular pressure tracings. Elevation of RVEDP has a 95% sensitivity for the diagnosis of constrictive pericarditis.

# 48 Primary Cardiac Tumors

*Brian T. Bethea*
*Adam Richter*

**KEY CONCEPTS**

- Epidemiology
  - Primary cardiac tumors are rare with an overall incidence of 0.02 percent. Malignant tumors metastatic to the heart are much more common with an incidence of 1.23 percent. About 25 percent of primary cardiac tumors are malignant (made up mainly of sarcomas), and about 75 percent are benign. Myxomas make up about 50 percent of benign cardiac tumors.
- Pathophysiology
  - Cardiac tumors arise from various cells in the heart. Clinical effects of these tumors are based chiefly on the size and location of the mass. Tumors can cause obstruction of valvular orifices as well as incompetence of valve leaflets, leading to symptoms of obstruction and congestive heart failure. In addition, friable tumors can embolize, causing systemic effects.
- Clinical features
  - The most common presentation of cardiac tumors is evidence of congestive heart failure due to obstruction and/or valvular insufficiency. Signs and symptoms of embolization include myocardial infarction, stroke, peripheral malperfusion, and mesenteric ischemia. Constitutional symptoms such as malaise, weight loss, myalgias, and fevers can occur due to elaboration of cytokines. Other presenting signs and symptoms can include arrhythmias, sudden death, chest pain, and pericardial tamponade.
- Diagnosis
  - A chest x-ray and electrocardiogram can suggest large tumors or those causing conduction disturbances. The mainstay of diagnosis, however, is echocardiography. Transthoracic echocardiography is an excellent screening tool, but transesophageal echocardiograaphy can provide higher resolution and more information about the dynamic effects of the mass during the cardiac cycle and the precise location of the tumor. Computed tomography (CT) scan and magnetic resonance imaging (MRI) are also useful in further characterizing cardiac masses and determining the depth of invasion in cases of malignant lesions.
- Treatment
  - The mainstay of treatment for the vast majority of cardiac tumors is surgical excision. Resection should be performed as quickly as possible after diagnosis given the risk of systemic embolization. Sarcomas portend a poor prognosis, but survival can be improved with surgical resection when technically feasible. In addition, some studies have suggested that chemotherapy and radiation therapy may enhance survival. Treatment of primary cardiac lymphomas is centered on chemotherapy with surgery only used for palliative debulking.
- Outcomes and prognosis
  - The prognosis of resectable benign tumors is usually very good with low recurrence rates depending on the type of tumor. In contrast, the prognosis of malignant lesions is dismal with the median survival being only 6 to 18 months, even with surgical resection or transplant.

## INTRODUCTION

### Definitions

Primary cardiac tumors are classified as neoplastic, hamartomatous, or hyperplastic. Typically, cardiac tumors originate from one of the following cell lines: mesenchymal, endothelial, neuroconduction system, autonomic nerve tissues, lymphatic tissues, or any other cell types normally found in the heart. Only tumors arising from cells within the myocardium and endocardium will be discussed in this chapter; masses arising from the pericardium will not be addressed.

## History

The first known documentation of a cardiac tumor was by Realdo Colombo in his studies of anatomy in 1559.[1] By 1865, both benign and malignant cardiac tumors had been described, including fibromas, rhabdomyomas, and sarcomas. It was not until 1952, however, that the first report of a premortem diagnosis of atrial myxoma was published. The first successful surgical resection of a myxoma followed in 1954.[2] Currently, echocardiography and other imaging modalities allow for the rapid and accurate diagnosis of cardiac tumors. Furthermore, sophisticated operative techniques for resection and subsequent reconstruction are well established.

## Overview

Cardiac neoplasms represent a rare disorder of the heart. Based on autopsy studies, the incidence of primary cardiac tumors is estimated to be 0.02 percent (ranging from 0.0017 to 0.25 percent).[3] Metastatic tumors to cardiac structures are more common than primary tumors with an estimated incidence of 1.23 percent in a large autopsy study. Common metastatic lesions include carcinoma of the lung, esophagus, breast, liver, melanoma, and lymphoma.[4,5] Regarding primary cardiac tumors, it is generally accepted that three-quarters are benign and one-quarter are malignant.[3] Among the benign tumors, atrial myxomas are by far the most common, accounting for one-half of all benign cardiac tumors, with other less common tumors being papillary fibroelastomas, lipomas, and rhabdomyomas. The most common malignant cardiac tumors are sarcomas.

Due to their relative infrequency, the diagnosis of cardiac neoplasms can be challenging. Clinical manifestations are independent of the pathologic subtype and are usually a function of the location of the tumor, propensity for systemic embolization, or nonspecific constitutional symptoms caused by elaboration of cytokines by the tumor. For example, patients may present with symptoms of either right- or left-sided heart failure secondary to the location and point of obstruction caused by the mass. Valvular masses can cause insufficiency or relative stenosis of the affected valve, and mechanical obstruction can occur due to the shape of the mass and its ability to occlude the valvular orifices, the vena cavae, or inflow from the pulmonary veins. Furthermore, left-sided masses can embolize to the systemic circulation, causing cerebrovascular events, myocardial infarction, and end-organ or limb malperfusion. Echocardiography is the initial diagnostic test of choice; however, EKG-gated computed tomography (CT) and magnetic resonance imaging (MRI) can provide useful additional information in terms of tumor diagnosis, extent, and involvement.

Treatment involves complete excision for curative therapy for benign tumors and even for malignant tumors when possible. The prognosis is generally excellent with benign resectable neoplasms; it remains dismal with malignant neoplasm, with survival generally around 1 to 2 years. Regardless, resection is recommended for cardiac sarcomas when feasible with adjuvant chemoradiation being protocol driven. Primary cardiac lymphomas are treated mainly with chemoradiation; surgical debulking can be performed for palliation.

# CLINICAL PRESENTATION

Cardiac tumors often present as an incidental finding on echocardiography or as a new finding during operations for other indications. Symptoms of cardiac tumors can be broken down into three general categories: cardiac manifestations, embolic phenomena, and systemic manifestations. As will be discussed in more detail, these symptoms are dependent on the location and mobility of the tumor within the heart, the propensity for systemic thrombus and/or tumor emboli, and the production of cytokines causing generalized symptoms.

## Cardiac Manifestations

Cardiac manifestations are the most common symptoms of cardiac neoplasms. The typical presentation can resemble congestive heart failure with dyspnea on exertion, peripheral edema, pulmonary edema, and orthopnea.[5] Congestive heart failure caused by cardiac tumors is usually due to mechanical obstruction related to pedunculated tumors that can obstruct the mitral valve or, less commonly, the tricuspid valve orifices. Masses that arise directly from cardiac valve tissue usually cause valvular insufficiency by preventing proper leaflet coaptation of the involved valve but may, in rare circumstances, cause valvular stenosis.

Cardiac tumors, most commonly rhabdomyomas and fibromas, can be the etiology of significant arrhythmias. The arrhythmias are usually due to involvement of the myocardium and conduction system. Tumors involving the atrial septum near the atrioventricular node can cause heart block, while masses in the ventricles can result in lethal ventricular tachycardias or fibrillation. Clinical manifestations of these arrhythmias can be anywhere along the range from palpitations, syncope, to sudden death.

Other cardiac manifestations are much less common. Angina pectoris and myocardial infarction can be a manifestation of tumor emboli. Rarely, left ventricular tumors can grow and compress any portion of the left coronary artery, causing an ischemic event as well. Pericardial effusions or tamponade may occur with hemangiomas, angiosarcomas, or lymphomas.

## Embolic Phenomena

Systemic embolization is a frequent clinical manifestation of friable tumors. The emboli can consist of fragmented tumor and/or thrombus formed on the surface of the mass. The clinical result of the embolization is a function of the vessels involved and the size of the emboli. Left-sided emboli may

travel anywhere in the systemic circulation and can present as an ischemic stroke, myocardial infarction, mesenteric ischemia, or limb malperfusion. Large tumor fragments can cause occlusion of larger arteries, including the abdominal aorta. Right-sided tumors can lead to pulmonary emboli and, if the embolic burden is large enough, pulmonary hypertension may develop. Importantly, right- or left-sided embolic events in patients with no known risk factors are cardiac in origin until proven otherwise.

One recent study found the overall rate of embolization due to primary cardiac tumors to be 25 percent. This same study found that papillary fibroelastomas, which are typically found on the mitral and aortic valves, are the most likely histological tumor type to embolize. Tumors in the left atrium or on the aortic valve have the highest embolic potential.[6] Given the relatively high risk of embolization, excision of all resectable cardiac tumors should be performed expeditiously.

### Systemic Manifestations

Constitutional symptoms such as fever, anorexia, malaise, myalgias, arthralgias, and diffuse erythematous rash can be associated with cardiac tumor. This constellation of symptoms is usually associated with myxomas and is believed to be secondary to interleukin 6 production.[7] Further, patients may be anemic or present with an increased erythrocyte sedimentation rate, C-reactive protein, and globulin levels. Notably, both the systemic manifestations and laboratory abnormalities usually resolve with resection of the mass.

### Physical Exam

The physical exam is usually nonspecific in patients with cardiac tumors. Evidence of congestive heart failure (peripheral edema, hepatomegaly, jugular venous distention, and rales) may be present. Signs of systemic emboli—pulseless extremity, neurologic deficits, abdominal pain out of proportion to exam—should be assessed in all patients presenting with a cardiac tumor. Furthermore, the diagnosis of a cardiac tumor should prompt one to consider the possibility of a distant primary with metastatic lesion to the heart. For example, malignant melanoma is one of the most common cancers metastasizing to the heart, so inspection of the skin should be carried out to locate any possible lesions.

Cardiac auscultation can reveal evidence of pulmonary edema, such as a split $S_1$ or loud $S_4$. Also, a holosystolic murmur at the apex can signify mitral insufficiency, while a new-onset diastolic rumble can be heard in the case of a tumor partially occluding the mitral valve orifice during ventricular filling. These murmurs can be heard in up to 50 percent of patients with cardiac tumors.[7] The specificity of the exam is increased when the intensity of the murmur changes with patient positioning. In addition, when a left atrial tumor prolapses through the mitral valve, a loud split $S_1$ can be heard due to delayed closure of the valve. A "tumor plop" can be also be heard, which is a small murmur heard early in diastole.[5]

## DIAGNOSIS

Echocardiography is the gold standard in the diagnosis of cardiac tumors. Transthoracic echocardiography should be the initial imaging modality and usually provides all necessary information. Transesophageal echocardiography, however, is utilized if questions remain after the transthoracic echo, is especially useful with smaller tumors, and can provide greater detail regarding the size, location and even the likely point of origin of the tumor. CT and MRI are especially useful with malignant and metastatic tumors and can be used to further characterize the nature and location of cardiac masses. Other adjunctive tests, such as plain chest radiography and electrocardiography, are used in the workup of cardiac tumors to assess associated pathology and conduction abnormalities, respectively.

### Electrocardiography

Electrocardiograms should be obtained in the workup of cardiac masses to assess for rhythm disturbances. Tumors involving the conduction system or atrioventricular node can cause atrioventricular block or supraventricular tachycardias. Masses found in the ventricles, such as fibromas, can cause lethal ventricular fibrillation or tachycardia as well. Despite these concerns, most patients with cardiac tumors maintain a normal sinus rhythm.

### Chest X-Ray

A plain chest film, while not specific for cardiac tumor, is an important part of the initial workup. Significant findings on chest x-ray are cardiomegaly due to either heart failure or the mass itself, compensatory hypertrophy/dilation secondary to valvular dysfunction, or enlargement of one of the cardiac chambers from a large mass. Additional notable findings include pulmonary edema secondary to congestive heart failure and additional lesions in the lungs or bone that suggest additional metastatic disease.

### Echocardiogram

Echocardiography, either transthoracic or transesophageal, is the mainstay of the diagnosis and evaluation of cardiac tumors. Transthoracic echocardiography is easy to perform, widely available, and can be used for screening in high-risk patients, such as those with a history of previous cardiac mass or the Carney complex (described later). While transthoracic echocardiography is excellent for determining the presence of a mass, transesophageal echocardiography can give more information regarding the location of the mass, the presence and morphology of a stalk, and the precise origin of the tumor. One advantage of echocardiography is the ability to give temporal as well as spatial resolution, thus evaluating

the motion of a pedunculated tumor in the cardiac chamber and its effect on normal contraction, valvular function, and blood flow during the cardiac cycle.

## Computed Tomography

With the advent of ECG-gated CT, this modality is being used more frequently to further characterize cardiac tumors. CT can detect areas of heterogeneity, calcification, or enhancement with contrast (important in the diagnosis of hemangiomas) and can yield information with regards to the amount of myocardial involvement. This is especially important in differentiating benign from malignant disease and aids in preoperative planning.

## Magnetic Resonance Imaging

MRI can provide information regarding the anatomic location of the mass as well as the extent of invasion of the cardiac wall or septum. MRI can give better resolution of the soft tissues, thus making it more effective at determining the extent of involvement of the cardiac walls. This can be invaluable in the evaluation of masses and the differentiation between benign and malignant lesions, thus obviating the need for open biopsies. Images taken real time can also give an impression of the functional disturbances caused by the mass.[5]

## Cardiac and Coronary Angiography

In the past, angiography was used to diagnose intracardiac tumors, but the use of angiography has declined dramatically with the widespread use of echocardiography and the recognized risk of tumor fragmentation due to the angiography catheter (Fig. 48-1). Coronary angiography should be considered in all patients undergoing cardiac mass resection to determine the presence of coronary artery disease and the need for simultaneous coronary bypass. Coronary angiography can also show if a tumor derives its vascular supply from a main coronary artery, which could suggest that a bypass of that artery may be necessary.

# BENIGN TUMORS

## Myxoma

Atrial myxomas comprise one-half of all benign primary cardiac tumors, far outnumbering any other tumor type. Approximately 75 percent arise from the left atrium, with the majority originating at the edge of the fossa ovalis. An additional 15 to 20 percent arise from right atrium, again largely at the edge of the fossa ovalis. Biatrial myxomas have been described; they likely represent tumor extension from one atrium to another through the foramen ovale. The final 3 to 4 percent of myxomas arise from the ventricles with bilateral ventricular involvement being extremely rare.[7] Most myxomas arise as solitary lesions but multifocal disease has been reported. When they do arise, the majority of cases of multiple myxomas are associated with a familial myxoma syndrome, such as the Carney complex of cardiac myxoma, adrenocortical tumors, and skin hyperpigmentation. Myxomas have little to no malignant or metastatic potential, although some rare cases of metastatic myxomas have been reported.[8]

## Epidemiology

Although myxomas have been reported in people of any age ranging from infancy to 95 years, the median age at diagnosis is 50, with the majority of cases being discovered in the third through sixth decades of life.[7,9] There is a clear female preponderance, with women making up about two-thirds of diagnosed patients.[9]

The vast majority of myxomas are sporadic, but 5 to 10 percent of cases demonstrate familial patterns of inheritance. These patients are more likely to have multicentric disease, recur after excision, occur in younger patients (mean age of 23.9), and are more likely to affect males with a male-to-female ratio of 2:1.[10,11] Originally described as the NAME (nevi, atrial myxoma, myxoid neurofibromata, ephelides) and then the LAMB (lentigines, atrial myxoma, mucocutaneous, and blue nevi) syndromes, the Carney complex describes the close association of cardiac myxoma, Cushing syndrome secondary to pigmented nodular adrenocortical dysplasia, cutaneous myxoma, myxoid mammary fibroadenoma, and pigmented spots on the skin. Genetic studies have determined that the Carney complex is due to a mutation at the chromosome 17q24 locus. This locus contains the PRKAR1A gene, which codes for the R1-α regulatory subunit of the cAMP-dependent protein kinase A. Nonsense or frameshift mutations of this gene result in decreased R1-α protein; how this contributes to tumorigenesis has not yet been elucidated. Of note, it was initially thought that a mutation on chromosome 2p was the source of the symptoms in one family studied, but further analysis demonstrated that this kindred had a mutation at the 17q24 locus as well.[11] This disease is inherited with an autosomal dominant pattern.

Given that patients with familial myxoma have an elevated recurrence rate of 12 to 22 percent, close follow-up with echocardiography is recommended.[7] First degree relatives of patients with the Carney complex should be screened for cardiac myxomas.

## Pathology

Macroscopically, myxomas fit into two categories based on their gross appearance: solid and gelatinous (Fig. 48-2A and B). Solid tumors appear firm and are usually pedunculated and located on the edge of the fossa ovalis. Gelatinous tumors appear softer and more friable with clear pink or green coloration. Gelatinous tumors also have a villous or lobed

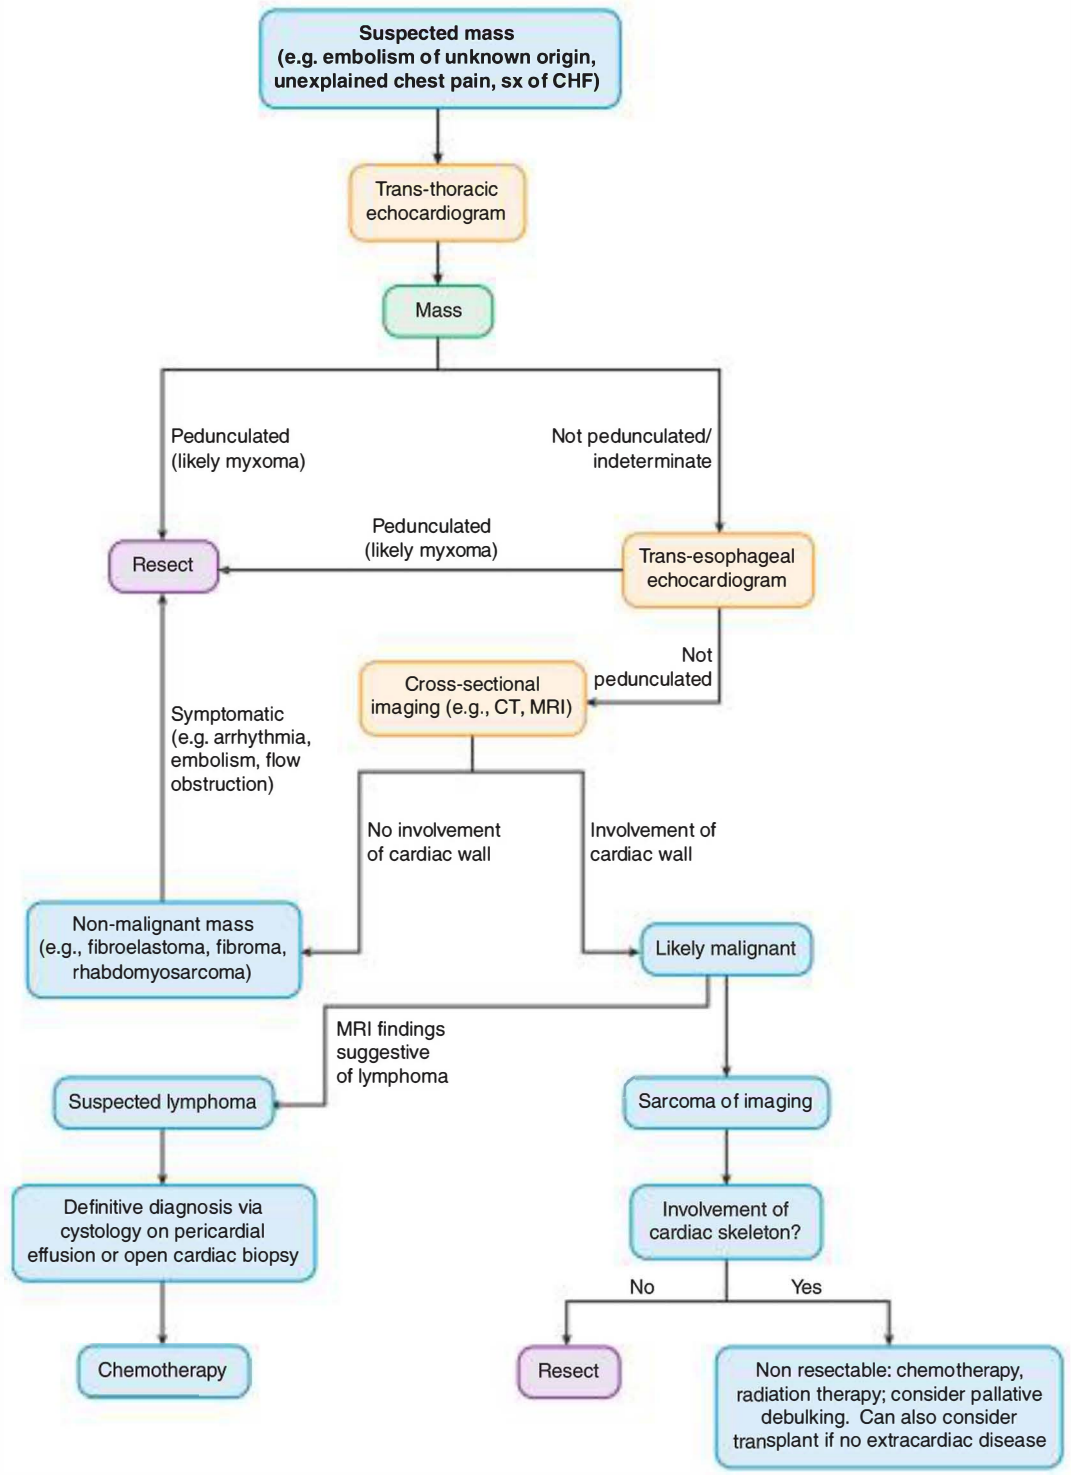

**FIGURE 48-1** Flow diagram describing the general workup and treatment of cardiac tumors.

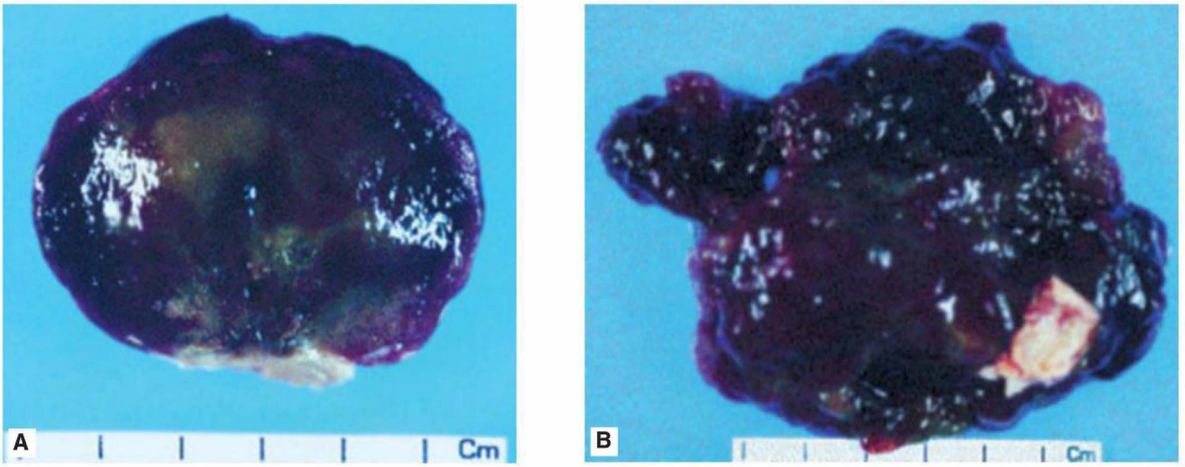

**FIGURE 48-2** Gross photographs of the two subtypes of atrial myxoma. Note the smooth, round edges in **A** as compared with the irregular, polypoid appearance of the tumor in **B**. The incidence of systemic embolism is higher with the polypoid subtype. (Reprinted from Ha JW, Kang WC, Chung N, et al. Echocardiographic and morphologic characteristics of left atrial myxoma and their relation to systemic embolization. *Am J Cardiol* 1999;83(11):1579–1582. With permission from Elsevier.)

appearance with thrombus development between the villi. These differences are not absolute, as some myxomas have characteristics of both types.[12] The clinical presentations can differ between the two, as solid tumors are more likely to present with symptoms of congestive heart failure and gelatinous tumors are more likely to embolize. These morphological differences can be seen on echocardiography.[13]

## Histology

Microscopically, myxoma cells are spindle-shaped with round or oval nuclei, prominent nucleoli, and extremely rare mitotic figures. Some cells are noted to have two nuclei. They are arranged in groups around capillaries within a myxoid stroma and can resemble endothelial cells. Also present are chronic inflammatory cells and hemosiderin-laden macrophages.[12] Areas of hemorrhage are common in both types of myxoma, but they are more common in solid tumors.[14] Necrosis and calcifications can be seen as well, up to 8.7 and 16 percent, respectively, in a study of 80 atrial myxoma resections performed at the Mayo Clinic. Other uncommon findings include bone and cartilage formation and glandular formations, including goblet cells and groups of cuboidal and columnar cells.[15]

The histogenesis of myxomas remains controversial. Initial hypotheses held that the myxomas actually arose from clot and represented highly organized thrombi. This view has largely been abandoned in favor of a neoplastic theory, although no definite progenitor cell has been implicated. Some studies have suggested that the tumors are endothelial in origin, supported by the fact that some cells will test positive for Factor VIII; it has been shown that only the cells lining vessels within the tumors have such staining properties. Presumably, these cells represent normal endothelium within the tumor and not neoplastic cells. The myxoma cells all stain strongly for vimentin, which suggests a mesenchymal origin. Also of note, many of the cells stained for S-100, a protein found in malignant melanoma as well as cells with chondromatous differentiation. Elements of smooth muscle have also been seen in myxomas; these are also located around vessels within the tumors and not dispersed within the myxomatous matrix. This has led investigators to conclude that myxomas likely arise from multipotent mesenchymal cells that may be embryological remnants.[16] An alternative hypothesis is that myxomas are actually hamartomatous in nature, rather than neoplastic (Fig. 48-3A and B).

## Treatment

The treatment of atrial myxomas is surgical excision and, in general, resection is curative. The finding of an atrial myxoma is an indication for surgery and should be done in an expedited elective fashion in order to minimize the risk of interval embolic events. The surgical approach is through a median sternotomy incision. Moderate hypothermia is used, and the patient is placed on bicaval cardiopulmonary bypass. Left atrial and ventricular myxomas are generally approached through the left atrium and right-sided lesions are approached through the right atrium. Alternatively, a transeptal approach has been advocated for left atrial myxomas, providing excellent exposure, and certainly should be the preferred approach for biatrial myxomas. Further, the transseptal approach has been reported to be associated with a reduced risk of postoperative arrhythmias.[14] Regardless of approach, most important is complete excision of the myxoma with a cuff of normal endocardium to decrease

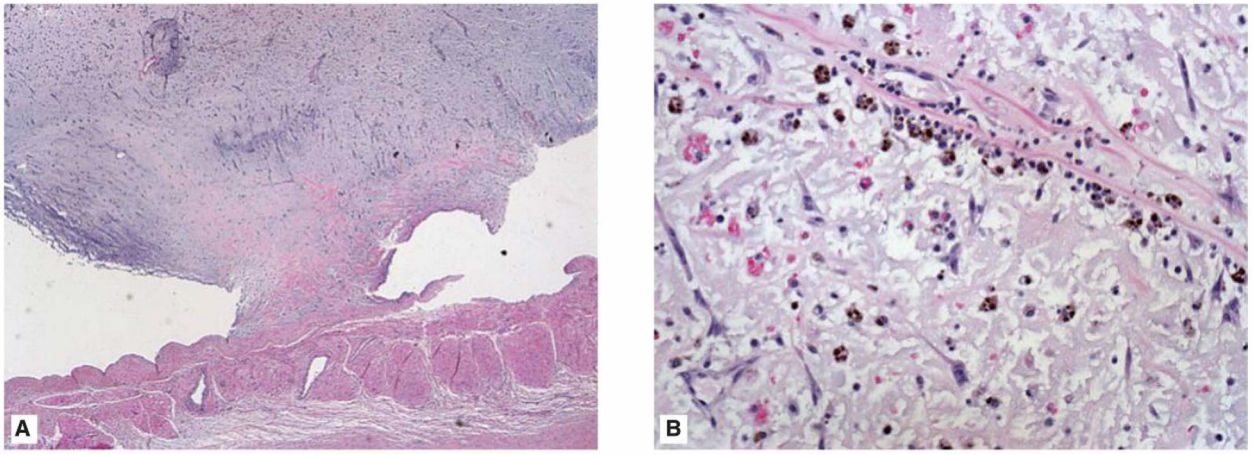

**FIGURE 48-3** Microscopic images of atrial myxoma. Note the stalk arising from the endocardium in **A**. **B** shows an area of remote hemorrhage with hemosiderin-laden macrophages. (Courtesy of Dr. Jonathan Baker, Department of Pathology, University of Texas Southwestern Medical Center.)

the chances of recurrence. The resulting defect is closed primarily if possible or patched with autologous or bovine pericardium. Lastly, all four chambers and valves should be inspected for metasychronous lesions before closing.

## Outcomes

The prognosis after complete myxoma resection is excellent, with the expected survival equivalent to that of the general population. Recurrence has been estimated to be about 3 percent in sporadic cases, but one recent study revealed a recurrence rate of up to 13 percent. Of note, this study did not differentiate between familial and de novo disease.[17] Recurrence has been has been thought to result from residual disease stemming from inadequate resection, concurrent disease undetected at the time of operation, or a subsequent separate tumorigenic event. As a result, postoperative screening with echocardiography is recommended, especially in patients with familial disease.

## Papillary Fibroelastoma

Cardiac papillary fibroelastomas or fibroelastic papillomas comprise approximately 10 percent of all benign primary cardiac tumors, although it has been suggested that they may be greatly underdiagnosed.[3,17] The vast majority arise on the aortic and mitral valves with the most common nonvalvular location being the left ventricle. Given their propensity for cardiac valves, these tumors make up about three-quarters of all valvular tumors. Multiple tumors are uncommon, but occur in up to 6 percent of patients, according to one large study.[18]

The majority of papillary fibroelastomas are found incidentally during echocardiography or at the time of surgery for other indications. When the tumors become symptomatic, the presentation is usually due to systemic embolization. Interestingly, pathologic examination of emboli in patients with papillary fibroelastoma only rarely yield evidence of the actual tumor, suggesting that the majority of embolic events are due to the dislodgement of associated thrombus. The location of the tumor is related to the symptoms and associated complications, with aortic valve tumors being more likely to cause myocardial infarction or sudden death and mitral valve tumors more commonly associated with systemic or cerebral embolic events.[19] Patients can also present with symptoms of congestive heart failure due to valvular stenosis or, less commonly, insufficiency due to interruption of the leaflets by tumor. As previously mentioned, sudden death occurs from complete obstruction of a valvular orifice or coronary artery occlusion from either aortic valve tumors adjacent to the ostia of the coronary arteries or embolic events to the coronary arteries.

## Epidemiology

Cardiac papillary fibroelastomas have been reported in patients of all ages from neonates to the elderly, but the frequency is highest in the fourth through eighth decades with a mean age at diagnosis of 60. Males have a higher incidence. No familial patterns of disease have been reported although a small number of cases have been found to be congenital. The tumors are slow-growing, but they can exhibit acute increases in size due to overlying thrombus formation.[18]

## Pathology

Macroscopically, fibroelastomas are about 1 cm in size and have many frond-like projections that are evident after immersing the tumor in saline. The fronds are suspended

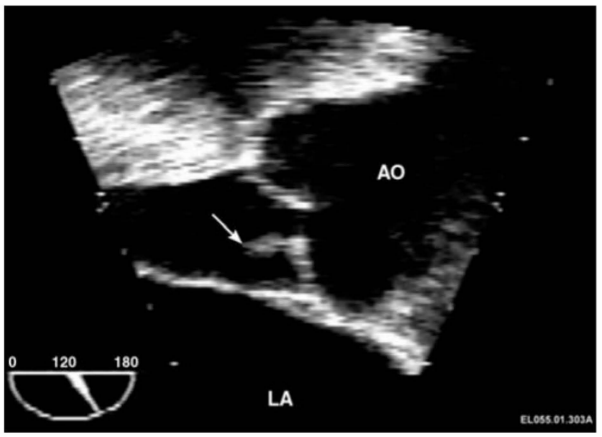

**FIGURE 48-4** Papillary fibroelastoma on the aortic valve on a long-axis view of a transthoracic echocardiogram (marked by arrow). (Reprinted from Ngaage DL, et al. Surgical treatment of cardiac papillary fibroelastoma: A single-center experience with eighty-eight patients. *Ann Thorac Surg* 2005;80:1712–1718. With permission from Elsevier.)

by a short pedicle that permits prolapse through valvular orifices (Fig. 48-4). Fibroelastomas tend to arise from the middle of the valve, rather than the edge (Fig. 48-5). This is in contrast to Lambl excrescences, which are common frond-like lesions found on the valve edges thought to represent organized thrombus due to minor endothelial damage at these sites. Fibroelastomas located on the atrioventricular valves tend to project into their respective atria, and tumors located on the semilunar valves tend to project into their respective arteries.[18]

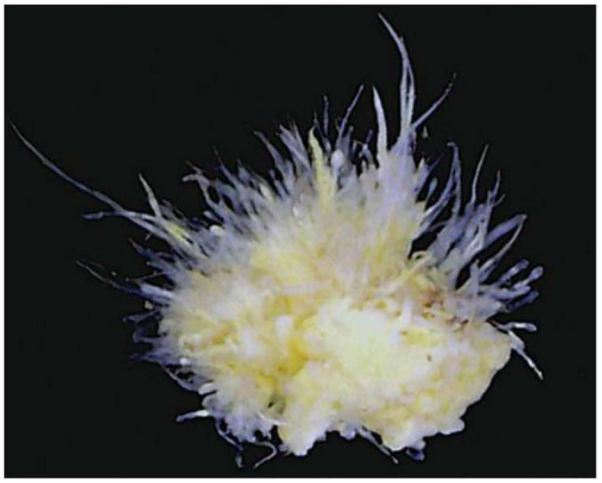

**FIGURE 48-5** Gross specimen of a papillary fibroelastoma underwater. Note the numerous fronds emanating from a central tumor. (Reprinted from Ngaage DL, Mullany CJ, Daly RC, et al. Surgical treatment of cardiac papillary fibroelastoma: A single-center experience with eighty-eight patients. *Ann Thorac Surg* 2005;80:1712–1718. With permission from Elsevier.)

## Histology

Microscopic examination of papillary fibroelastomas demonstrates an acellular myxomatous stroma surrounding an eosinophilic paucicellular core with a flat and cuboidal endothelial lining (Fig. 48-6A and B). They are distinct from myxomas in that they are avascular and do not have the syncytia of spindle-shaped myxoma cells. Immunohistochemical analysis yields the cells comprising the outer lining staining positive for Factor VIII, CD34, and vimentin. The cells in the core of the tumor stain positively for vimentin and S-100, but are negative for CD34 and Factor VIII, two markers for endothelial cells. The stroma demonstrates linear staining of type IV collagen immediately below the endothelial layer that becomes more granular as it gets closer to the core. Also present are linear arrangements of elastin in a similar linear configuration. Among the elastic fibers is the myxoid stroma comprised mainly of an acidic mucopolysaccharide.[20]

## Histogenesis

As with cardiac myxomas, the histogenesis of papillary fibroelastomas is unclear. They have been described as hamartomas, representations of organized thrombi, reactions to endocarditis, or benign neoplasms. Papillary fibroelastomas have been compared with Lambl excrescences, which are also frond-like projections arising from the edges of cardiac valves that are secondary to minor endocardial injuries; these arise from small thrombi and have been shown to be common in autopsy series. In contrast, papillary fibroelastomas are more rare, arise from the middle of the valvular surface, and can arise from areas of endocardium other than the valve edge. Microscopically, organized thrombi do not demonstrate any elastin deposition, and while they do demonstrate areas of proliferating fibroblasts, there is also evidence of capillary formation in the thrombi, which is not present in fibroelastomas.[20] There is some evidence that chronic viral endocarditis may play a role in the development of fibroelastomas, as dendritic cells and remnants of cytomegalovirus have been found within the layers of collagen and elastin in the acellular stroma.[18]

The neoplastic theory of papillary fibroelastomas is supported by what appears to be proliferation by the surface endothelial cells. This is evidenced by the continual production of layers of type IV collagen, which has been demonstrated by immunohistochemical staining. The origin of the neoplastic cells, however, is unknown. The presence of CD34, vimentin, and Factor VIII suggest an endothelial origin, but positive staining for S-100 is inconsistent with an endothelial progenitor. S-100 is a protein of unknown function that is found in malignant melanoma cells as well as chondromatous cells. In the case of cardiac myxomas, the presence of S-100 is thought to support the premise that the myxoma cells are multipotent, with endothelial cells giving rise to papillary fibroelastomas. The data are currently incomplete, and no definite conclusion regarding the origins of papillary fibroelastomas has been established.

In **B**, a flat endothelial lining surrounds the hyalinized stroma. (Courtesy of Dr. Jonathan Baker, Department of Pathology, University of Texas Southwestern Medical Center.)

## Treatment

Treatment of fibroelastomas is complete surgical excision. The surgical approach is similar to that of myxomas and all chambers and valves should be explored for synchronous lesions. Valve repair or replacement may be necessary depending on how much of the valve is resected. For patients who are not operative candidates, oral anticoagulation has been suggested if feasible in an effort to decrease the risk of systemic embolization from thrombus accumulating on the surface of the tumor. Although oral anticoagulation makes intuitive sense, there are no guidelines to recommend the widespread use of warfarin in this patient population.[19]

## Outcome

The long-term prognosis after complete resection of papillary fibroelastomas is favorable. Life expectancy approaches that of the general population, and the recurrence rate has been shown to be low to nonexistent.[17,19]

## Rhabdomyoma

Rhabdomyomas are most commonly found in children, making up the most common primary cardiac tumor in the pediatric population. They are found in roughly 10 percent of the general population and as such constitute one of the more common benign tumors in adults as well.[3] Most rhabdomyomas arise in the ventricular walls; rarely, they may originate from the atria. Symptoms are usually due to either mass effect resulting in obstruction of blood flow or cardiac conduction abnormalities. Common electrocardiographic changes include bundle branch block, preexcitation, and atrioventricular blocks.[9]

Cases of rhabdomyoma represent a cardiac manifestation of tuberous sclerosis in up to 50 percent of cases.[9] Tuberous sclerosis is an autosomal dominant disease that involves the loss of function of two tumor suppressor genes, TSC-1 hamartin and TSC-2 tuberin. TSC-1 is found on chromosome 9q34 and TSC-2 is found on chromosome 16p13.3. Other manifestations of tuberous sclerosis are brain hamartomas, hyperpigmented skin lesions, pancreatic lesions, and retinal lesions.

Cardiac rhabdomyomas are not capable of mitotic division. The natural history of rhabdomyomas is usually spontaneous regression. For this reason, current therapy involves watchful waiting with surgical intervention only if obstructive symptoms develop, or if conduction abnormalities prove refractory with medical management.

## Fibromas

Cardiac fibromas are solitary benign lesions that arise most frequently in the ventricles with the left being more commonly involved than the right. They arise from fibroblasts in the myocardium and behave similarly to fibromas found in other parts of the body. Children are most commonly afflicted. The most common presentation is consistent with congestive heart failure, but fibromas can also trigger malignant ventricular arrhythmias with sudden death or syncope. Angina pectoris can be due to displacement or occlusion of the coronary arteries by the tumor. Electrocardiography often reveals signs of ventricular hypertrophy, and plain chest radiography can show cardiomegaly with an abnormal contour of the heart and calcifications within the tumor. Calcifications noted on plain film or CT scan are highly suggestive of fibroma versus other cardiac neoplasms.[21] Diagnosis is made with echocardiography.

Gross inspection of the tumor reveals a firm, white mass that usually arises from the ventricle. Histologic evaluation reveals well-circumscribed but not encapsulated tumors located in the myocardium. They are made of fascicles of spindle-shaped cells surrounded by copious amounts of collagen. Cytologic atypia and mitotic figures are usually absent. Areas of calcification are seen in about 56 percent of tumors, which can sometimes be seen on x-ray.[15]

Treatment for cardiac fibromas is surgical excision. Usually, a plane can be developed between the tumor and the myocardium facilitating mass removal. Reconstruction of the ventricular septum is often required and can be accomplished with autologous or bovine pericardium or with a Dacron patch dependent on patient and size factors. One particular challenge occurs when the tumor is located on the superior ventricular septum and passes deep to the left coronary artery or if the mass intimately involves the papillary muscles. In these cases, partial resection of the fibroma has been shown to be effective for alleviating symptoms. In these cases, reoperation has not been necessary, as the residual tumor does not appear to grow to its original size. In addition, partial resection has been shown to eliminate malignant arrhythmias. In cases when the papillary muscles are involved, mitral valve repair or replacement may be indicated. Cardiac transplantation has been suggested for treatment for anatomically complicated fibromas, but given that partial resection may acceptably eliminate the symptoms and risk for sudden death, transplant should only rarely be performed for benign fibromas.[21]

## Lipomas

Cardiac lipomas are benign fatty tissue tumors that make up about 10 percent of benign primary cardiac tumors.[3] They are most often found on the epicardial surface, but they have also been noted to arise in the interatrial septum. Usually, these lesions are found incidentally and do not have any clinical significance. Symptoms, when present, are due to mass effect and obstruction. Microscopically, lipomas are encapsulated and appear as homogenous mature adipocytes with fine septations. Mitoses are rare to nonexistent, and small areas of inflammation can be seen. These areas can be difficult to distinguish from lipoblasts, which would indicate liposarcoma rather than benign lipoma.[22] Differentiation from malignant liposarcoma preoperatively depends upon imaging by CT or MRI to determine if the mass is homogenous, which would suggest a benign lipoma, A heterogenous lesion would be suggestive of a malignancy, which would be an indication for excision. Ulitmately, surgical resection is indicated for symptomatic lesions or when a liposarcoma is suspected. Otherwise, no specific treatment is necessary for cardiac lipomas.

## Lipomatous Hypertrophy

Lipomatous hypertrophy refers to the hyperplasia of naturally occurring fat in the interatrial septum that is continuous with epicardial adipose tissue and, as such, does not constitute true neoplasia. The incidence has been suggested to be as high as 2.2 percent. A higher incidence is associated with obesity and increasing age, with most patients being older than 60 years at the time of presentation. Interestingly, there appears to be an association between female gender and larger lesions. The interatrial septum can become quite thickened to over 3 cm and potentially result in a broad-based mass lesion with atrial filling defects involving the right atrium more commonly than the left. Most cases are asymptomatic and are detected incidentally on transesophageal echocardiography or at autopsy. Presenting symptoms usually include congestive heart failure due to mass effect on the atria, obstruction of the superior vena cava, or intractable supraventricular arrhythmias. There have been some reports of valvular disruption and sudden cardiac death as well.

Grossly, lipomatous hypertrophy appears similar to normal epicardial fatty tissue that spares the fossa ovalis. This creates a bilobed appearance on transverse section of the interatrial septum and on CT scan. It can also appear in the free wall of the right atrium, extend into the root of the aorta, or extend into the atrioventricular groove. Microscopically, the lesions appear to be normal mature adipocytes admixed with brown fat adipocytes marked by multiple vacuoles. Interspersed in the adipocytes are hypertrophied cardiac myocytes with multiple nuclei and cytoplasmic vacuolization. In contrast to lipomas, there is no capsule containing the mass.[22]

Since most lesions are found incidentally, surgery is not usually indicated for lipomatous hypertrophy. Excision is appropriate for patients with congestive heart failure due to atrial compression, atrial arrhythmias refractory to medical management, or valvular dysfunction due to the mass.

## Hemangioma

Hemangiomas are benign tumors that can arise from endothelial cells to form channels of blood. They can be found within the pericardium, myocardium, or endocardium and can originate from any chamber. Hemangiomas comprise approximately 2.8 percent of benign cardiac tumors, and have an equal age distribution and a female preponderance.[23]

Symptoms of hemangiomas can include heart failure due to obstruction, atypical chest pain, arrhythmias with sudden death, pericardial effusion, valvular obstruction, or embolic events. Electrocardiography is usually normal. Diagnosis is made with transthoracic echocardiography and the tumor can be further characterized with transesophageal echocardiography if necessary. On a contrast CT scan, initial imaging shows a filling defect in the affected chamber but follow-up imaging after 5 min shows the tumor enhancing with Hounsfield units equivalent to that of the surrounding blood in the heart. This suggests the highly vascular nature of the tumor and is similar to the CT findings of hepatic hemangiomas. For preoperative planning, an MRI can give additional information with respect to the soft tissue planes around the tumor.[23]

The majority of hemangiomas are about 2 to 3.5 mm in size and can be either polypoid or sessile. Three histological

subtypes of hemangioma exist: cavernous, arteriovenous, and capillary type. The first is marked by many large thin-walled vessels, the second by dysplastic arteries and veins, and the last by smaller vessels similar in appearance to capillaries. These tumors are not encapsulated.[23]

Resection can be technically challenging depending on the location of the tumor and the degree of infiltration into the myocardium. Sometimes, reconstruction of the interatrial septum or even the free wall may need to be performed. Prognosis is good after resection, but long-term postoperative follow-up is warranted to monitor for recurrence.

### Cystic Tumors of the Atrioventricular Nodal Region

These rare lesions, formally referred to as mesotheliomas of the atrioventricular node, represent cystic lesions thought to be epithelial rests of endodermal origin that arise immediately adjacent to the atrioventricular node. The most common presenting symptom is sudden death due to ventricular arrhythmias and, accordingly, most are found on autopsy studies. Interestingly, they have been discovered in patients from infancy to 70 years of age, and older patients presenting with sudden death often do not have a history of syncope or palpitations.[24] Electrocardiography usually reveals various degrees of heart block and QRS narrowing. The lesion can be detected by MRI, CT, or echocardiogram. Treatment involves resection with pacemaker placement. There are only rare reports of antemortem detection and successful surgical treatment in the literature.[25]

### Cardiac Neurilemomas

Cardiac neurilemomas, or schwannomas, are rare benign tumors that are thought to arise from the cardiac branches of the vagus nerve or the cardiac plexus. They normally arise on the right side of the heart near the interatrial septum. Only 14 cases have been reported in the literature, and these cases show a female predominance (10 females and 4 males) with age ranging from 12 to 72 years. They can be on the exterior of the heart and cause compression of the pulmonary veins and superior vena cava. Diagnosis is made histologically with the demonstration of areas of spindle-shaped cells with rare mitoses and strong uniform staining for S-100. Of note, frozen sections sent intraoperatively can be easily misinterpreted, and the final diagnosis must rest on the formal pathological and immunohistochemical studies on the final specimen.[26] Treatment is surgical excision, and the prognosis is excellent with complete resection.

## MALIGNANT TUMORS

One quarter of all primary cardiac neoplasms are malignant.[3] Of these, sarcomas are by far the most common with a very small percentage of primary cardiac lymphomas essentially comprising the rest. Cardiac malignancies generally portend a poor prognosis, and almost all patients eventually succumb to their disease. The median survival from time of diagnosis has been reported to be 6 to 18 months. When technically feasible, surgical resection is the treatment of choice, but unfortunately this is rare as most are diagnosed after the tumor has reached an advanced state. Debulking of these tumors for obstructive symptoms can provide palliation but is controversial. Although chemotherapy plays a dominant role in the treatment of lymphoma, the role of adjuvant chemoradiation in sarcomas has not been clearly defined.[27]

Differentiating benign from malignant disease preoperatively can be difficult but is crucial as earlier surgical intervention provides a better chance for cure. Features that suggest malignancy are rapid growth rate, local invasion on imaging, intracavitary lesions that also involve the chamber wall, and hemorrhagic pericardial effusion. These symptoms, however, are nonspecific and can be seen with benign lesions as well.

### Sarcomas

Sarcomas comprise the vast majority of primary cardiac malignancies and are the second most common type of primary cardiac tumor after myxomas. Believed to arise from pluripotent mesenchymal cells, several histologic subtypes of sarcomas exist with angiosarcoma being the most common. Other notable histologies include rhabdomyosarcoma, liposarcoma, myxosarcoma, leiomyosarcoma, malignant fibrous histiocytoma, and synovial cell sarcoma, but many are undifferentiated and are not otherwise classifiable. Most sarcomas arise on the left side of the heart, with the exception of angiosarcomas, which tend to arise on the right side.[2,27] Notably, surgical resection is related more to the size and location of the tumor and the associated involved structures rather than the histological subtype of the tumor.

Clinically, the most common presenting symptom is dyspnea on exertion due to an obstructing tumor. Like other cardiac tumors, sarcomas can present with symptoms due to embolic events, chest pain, rhythm disturbances, or constitutional symptoms. In addition, they may present with evidence of metastasis to bones or to skin.[2]

### Epidemiology

Primary cardiac sarcomas have an incidence between 16 and 35 percent of all cardiac tumors with an equal gender distribution. The median age at presentation is 41 years, and the disease is most commonly diagnosed in young- to middle-aged adults with children and infants being affected only rarely.

### Pathology

All sarcomas arise from mesenchymal cells but are classified based upon the differing patterns of differentiation.

Undifferentiated sarcomas do not have enough characteristic histological features to place them in a specific subtype.

Angiosarcomas have endothelial differentiation. They are similar to benign hemangiomas in appearance, but they demonstrate more atypia in the cells lining the vascular lumens and more mitotic figures. The tumor can also create capillary channels that do not have any discernible lumen. In less differentiated angiosarcomas, the endothelial origin of the cells is not as evident, and the cells do not form well-defined vascular structures. In these cases, the pathologic diagnosis can be inferred by lakes of blood within the tumor. Although not sensitive, it should be noted that angiosarcoma cells will stain positive for factor VIII due to their endothelial origin.[2]

Cardiac malignant fibrous histiocytomas appear similar to those found in other parts of the body. Two tumor cell types predominate: spindle-shaped fibroblastic cells with intracytoplasmic filaments and enlarged endoplasmic reticulum and the more pleomorphic histiocytoid cells marked by scattered lysosomes and lipid inclusions. Malignant fibrous histiocytoma can appear with a myxoid background and can also have areas that are paucicellular or acellular that can appear similar to myxomas, leading to a pathologic misdiagnosis. In general, however, malignant fibrous histiocytomas are more cellular and show a higher degree of atypia. In addition, the vascularity differs in the two types of tumor: in myxomas, the vessels are small, thin-walled capillaries, whereas in malignant fibrous histiocytomas, the vessels are thicker walled and have more prominent, branching vessels.[2]

Fibrosarcomas histologically appear similar to fibroblasts. They are polypoid tumors that can be intracavitary and invade the myocardium. The cells appear spindle-shaped, similar to malignant fibrous histiocytoma; the pleomorphic histiocytoid cells are not present. The cells are visible in a background of collagen or myxoid matrix.

Rhabdomyosarcomas are a rare type of sarcoma and can be found in any chamber of the heart with equal incidences. They can become quite large, up to 10 cm. On microscopic examination, rhabdomyosarcomas can appear similar to striated muscle. The typical myocyte structure of thick and thin filaments can be variably preserved with visible Z-bands, abundant glycogen, and many mitochondria. The presence of rhabdomyoblasts will confirm the diagnosis.[2]

## Surgical Treatment

As with the majority of cardiac tumors, complete surgical excision is the only proven therapy for primary cardiac sarcomas. When technically feasible, complete resection of the tumor can result in a median survival of almost 24 months.[28] The surgical techniques are similar to those for benign tumors. Patients are placed on cardiopulmonary bypass with superior and inferior vena cava cannulation and aortic return when possible. Larger lesions require more radical resection, which can result in the complete excision of atria, roots of the aorta or pulmonary artery, pericardium, or sections of either ventricle. Reconstruction of these structures can be done with bovine or autologous pericardium or synthetic materials such as Dacron. One institution found that either atrium could be replaced in its entirety, and up to 30 percent of the right ventricle could be patched while still maintaining adequate cardiac function. A major sign of unresectability is involvement of the fibrous cardiac skeleton. Coronary bypass may be necessary if ligation of a coronary artery is required due to tumor involvement. One aggressive surgical technique that has been utilized is cardiac autotransplation, whereby the heart is explanted from the mediastinum and the operation is performed on the back table before the heart is reimplanted into the chest. In addition to resecting the cardiac tumor, metastasis to the lungs can be surgically treated with lung parenchymal sparing resections. Adding these procedures, however, may increase operative mortality.[28]

In the absence of metastatic disease, cardiac transplantation has been used as a potential therapy for locally unresectable cardiac tumors. Cardiac transplantation has been shown to significantly add to survival and it has been suggested that postoperative chemotherapy may be of benefit. One strategy that has been employed is the identification of a proper donor allograft and a backup recipient. The patient is then taken to the operating room and resection of the cancer is attempted prior to allograft recovery. If resection is determined to not be feasible then a standard cardiac transplantation is performed. If resection is deemed to be possible then the donor allograft can be implanted into the backup recipient.[29] Although controversial, palliative debulking of sarcomas has been reported for cases of intracardiac mechanical obstruction or obstruction of the pulmonary artery.

## Medical Therapy

Both chemotherapy and radiation therapy have been employed in the treatment of cardiac sarcomas, but their role in treatment is still unclear. Adjuvant chemotherapy with paclitaxel, doxorubicin, ifosfamide, gemcitabine, or taxoterene is commonly used. Due to the low overall incidence of the disease, no studies exist that can definitively support the use of chemotherapy; chemotherapy should be considered on a case-by-case basis. Despite this inherent weakness in the literature, the existing data has suggested that chemotherapy with multiple agents may enhance the survival advantage achieved with surgery. Furthermore, radiation therapy administered postoperatively may increase survival as well. Neoadjuvant chemotherapy has also been suggested to decrease the size of the tumor to make the resection more technically feasible, but there are no data currently to make such a recommendation. For patients in whom surgery is not possible due to the extent of disease, significant comorbidities, or prohibitive tumor anatomy, treatment is purely palliative.

## Outcomes

The prognosis of primary cardiac sarcoma is dismal. Without surgery, median survival has been reported to be 10 months.

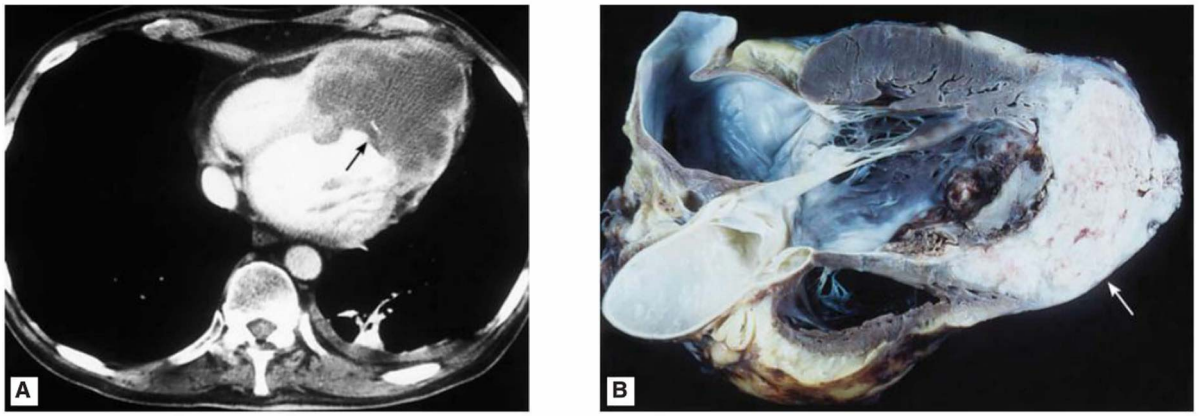

**FIGURE 48-7** CT scan demonstrates a large left ventricular lymphoma (marked by arrow) involving the cardiac wall in **A**; **B** demonstrates an autopsy specimen of a left ventricular lymphoma. (Reprinted from Araoz PA, Eklund HE, Welch, TJ et al. CT and MR imaging of primary cardiac malignancies. *Radiographics* 1999;19:1421–1434. With permission from the Radiological Society of North America.)

If complete resection is performed, the median survival is improves to 23.5 months.[28] Cardiac transplantation has been shown to improve survival, but more data are needed to fully analyze the effects of multimodality therapy.

## Lymphoma

Primary lymphoma of the heart, defined as the presence of cardiac lymphoma without any evidence of extracardiac disease, is extremely rare. It constitutes only 1.3 percent of primary cardiac tumors and less than 0.5 percent of all extranodal lymphomas. In contrast, lymphoma with secondary cardiac involvement, defined as cardiac lymphoma in the setting of nodal or other organ involvement, is common, with up to 20 percent of non-Hodgkin lymphoma patients having cardiac involvement at autopsy. B-cell differentiation is the most common (accounting for up to 80 percent cases of primary cardiac lymphoma in immunocompetent patients), but there have been reports of cardiac T-cell lymphoma as well. The mean age at presentation is 60 years. The tumors arise most commonly in the right atrium with the right ventricle being the second most common location. However, it should be noted that, in up to 75 percent of cases, multiple cardiac chambers are involved.[30]

Clinical presentation can be varied with most patients presenting with symptoms of right-sided heart failure. Other presenting symptoms can include pleuritic pain, syncope, an embolic event (usually pulmonary, given the predilection for right-sided tumors), pericardial effusion or tamponade, and pleural effusion. Constitutional B symptoms can also be present, but are relatively uncommon. Serum studies may show an increase in lactate dehydrogenase and erythrocyte sedimentation rate. Electrocardiography may demonstrate nonspecific findings, such as atrioventricular block.

As with other cardiac tumors, cardiac lymphomas can usually be evaluated with transthoracic echocardiography, reserving transesophageal echocardiography for better characterization and description. Cardiac CT can aid in defining pericardial involvement and extracardiac foci of disease (Fig. 48-7A and B). MRI, however, is considered the best modality for diagnosing cardiac lymphomas as well as monitoring tumor response to chemotherapy. On T1-weighted imaging, the tumor will appear as poorly delineated, slightly hypointense, heterogenous lesions. T2-weighted imaging renders the tumor isointense to the surrounding myocardium. Diagnosis can also be made by studying the cytology of drained pericardial or pleural effusions. Atypical lymphoid cells can be present in the fluid, and the diagnosis of lymphoma can be made with immunohistochemical staining. In patients in whom cardiac lymphoma is suspected, but there is no accompanying effusion to analyze, biopsy via exploratory thoracotomy can make the diagnosis.[30] Unlike other tumors of the heart, a firm diagnosis of lymphoma is necessary because treatment will not be surgical.

## Treatment

In contrast to other cardiac tumors, surgical excision is not the first-line treatment for cardiac lymphoma. Chemotherapy with anthracycline and anti-CD-20-based treatment are the mainstays of therapy,[9] and radiation therapy has been shown to increase survival. Surgical debulking has been used for relief of obstructive symptoms for palliation, but resection is not recommended as a primary treatment modality. Cardiac transplantation has been reported and is associated with some success.[30]

## Outcome

Due to the often late diagnosis, primary cardiac lymphoma generally carries a poor prognosis. Without therapy, survival is around 1 month. With an effective chemoradiation regimen, survival can be as long as 5 years.[30]

## PRIMARY CARDIAC TUMORS BOARD REVIEW QUESTIONS (CHAPTER 48)

1. The primary treatment of which of the following tumors does not involve surgical excision?
   A. Myxoma
   B. Papillary fibroelastoma
   C. Rhabdomyoma
   D. Liposarcoma
   E. Rhabdomyosarcoma

2. A 10-year-old boy presents to the ER after a syncopal episode. He denies any chest pain, but his mother reports that he is not able to run as much as other children because he has trouble catching his breath. EKG does not show any abnormalities, but the chest x-ray shows an enlarged left ventricle with calcifications in the same region. Echocardiogram demonstrates a left ventricular mass that seems to involve the papillary muscles. What is the best management of this mass?
   A. Medical therapy with β-blockers and/or calcium channel blockers
   B. Attempt a complete resection of the mass with autotransplantation
   C. Cardiac transplantation
   D. Partial resection of the mass
   E. Medical therapy with oral anticoagulation

3. A 42-year-old female presents to the clinic with complaints of worsening dyspnea on exertion. EKG and chest x-ray are normal. Transthoracic echocardiogram demonstrates a left atrial pedunculated mass with a short visible stalk arising from the interatrial septum. What is the most appropriate management of this tumor?
   A. Proceed to surgery for excision of the tumor.
   B. Obtain EKG-gated CT scan to further evaluate the anatomy of the tumor.
   C. Obtain cardiac MRI to determine if there is any involvement of the interatrial septum and right atrium.
   D. Provide medical therapy with a β-blocker and oral anticoagulation with repeat echocardiogram in 6 months.
   E. Obtain an angiogram of the left atrium and ventricle to determine the size of the mass and its relation to the fossa ovalis.

4. Which of the following therapies for cardiac sarcoma is associated with the longest survival?
   A. Chemotherapy with Doxorubicin, Paclitaxel, and Gemcitabine
   B. Radiation therapy alone
   C. Radiation therapy with chemotherapy
   D. Resection using the autotransplantation technique
   E. Surgical debulking of the tumor to relieve associated mitral valve orifice obstruction

5. Which of the following characteristics would render a primary sarcoma of the heart unresectable?
   A. Involvement of the mitral valve annulus
   B. Involvement of two-thirds of the left atrial wall
   C. Involvement of two-thirds of the right atrial wall
   D. Involvement of the right ventricular free wall
   E. Involvement of the aortic valve

## ANSWERS

1. **Answer: C.** Surgical excision is the mainstay of management of most benign cardiac tumors as well as sarcomas when feasible. Rhabdomyomas, however, are unable to proliferate, and as such, will usually spontaneously regress. Resection is only indicated in cases of severe obstruction and failure to regress. Rhabdomyosarcoma, like other sarcomas, is best treated surgically if detected at an early stage.
2. **Answer: D.** This case likely represents a ventricular fibroma. These tumors are common in children and present with symptoms of heart failure and arrhythmias. Calcifications noted on chest x-ray are highly suggestive of fibroma. While complete excision is the best therapy, partial excision has been shown to reduce symptoms as well when the mass is anatomically difficult to resect. Medical therapy is unlikely to be helpful in this patient. A radical solution, such as autotransplantation, is not necessary in this case as partial resection will suffice. Cardiac transplantation has been described as an option for ventricular fibroma, but should only be used as a last resort when there are no other surgical options.
3. **Answer: A.** The presence of a stalk arising from the interatrial septum is highly suggestive of an atrial myxoma. With this information from an echocardiogram, no more workup is necessary for the mass. The only other study to be considered would be a coronary angiogram to determine the need for a simultaneous coronary artery bypass graft. Given the propensity for embolization, myxomas should be resected expediently.
4. **Answer: D.** Cardiac malignancies have a very poor prognosis. The only proven therapy to significantly prolong survival is resection. Chemotherapy and radiation therapy have been shown to potentially prolong survival when combined with surgery, but they have not been shown to prolong survival alone. Surgical debulking is a palliative procedure that is not intended to increase survival.
5. **Answer: A.** Any of these scenarios would make resection of the mass difficult. The single-most important factor is the involvement of the fibrous skeleton of the heart. Either atrium can be replaced with pericardium (autologous or bovine) or Dacron, as can up to 30 percent of the right ventricle. The aortic root can also be replaced if necessary. Involvement of the mitral valve annulus would likely involve the fibrous skeleton of the heart and therefore would not be resectable.

# The Immunobiology of Thoracic Transplantation[1]

*Marc K. Halushka*
*William M. Baldwin III*

**KEY CONCEPTS**

- The major histocompatibility complex (MHC) consists of a genomic region that encodes a large and diverse group of proteins that are expressed on all cells. The two major classes of MHC molecules include class I molecules that are found on all nucleated cells and present antigen to CD8 positive ($CD8^+$) "cytotoxic" T cells and natural killer (NK) cells. Class II MHC molecules occur on antigen presenting cells and present antigen to CD4 positive ($CD4^+$) "helper" T cells.
- Normal development of immunotolerance occurs primarily in the thymus whereby T cells displaying different T-cell receptor complexes interact with thymic epithelial cells.
- Antigen presenting cells (APCs) are the most potent initiators of alloimmune responses because they express high levels of both MHC class I and class II antigens. APCs also express costimulatory molecules that provide secondary signals necessary for expansion of the T-cell response to alloantigens.
- T-cell receptor activation by MHC activates calcineurin. Calcineurin, in turn, activates a transcription factor that increases the interleukin-2 (IL-2) production and other cytokines.
- Secreted IL-2 binds to immune cell surface IL-2 receptors (IL-2R) and stimulates expansion of the local immune cell population (predominately T cells), resulting in increased inflammatory cells in the donor organ and injury manifested as epithelial cell or myocyte death.
- B cells mediate the antibody response to alloantigen, specifically donor endothelial cells. Antibody binding to alloantigen activates a complement cascade that causes endothelial injury resulting in interstitial hemorrhage, microthrombosis, and an influx of inflammatory cells.
- Hyperacute rejection occurs within the first 24 h after transplantation and is generally dependent on the presence of preexisting anti-human leukocyte antigen (anti-HLA) antibodies that coat the endothelium and activate complement.
- One known mechanistic pathway of bronchiolitis obliterans syndrome, or chronic lung allograft rejection, is the sensitization of $CD4^+$ T cells to MHC class I and class II molecules. Much of the resultant lung injury is from indirect pathway activation.
- Chronic allograft vasculopathy observed in cardiac allografts is thought to result from injury to the coronary artery endothelium. Sources of injury include immunologic (e.g., innate, T-cell–mediated, antibody-mediated) and nonimmunologic (e.g., diabetes, obesity, hyperlipidemia, hyperhomocysteinemia, and CMV) factors.
- During the first year after transplantation, acute rejection is noted in about 25 percent of heart transplant recipients and 36 percent of lung transplant recipients.

## OVERVIEW OF CHAPTER

After the technical challenge of lung or heart transplantation has been successfully achieved, the process of maintaining a healthy graft begins. For this, a general understanding of the immunobiology of thoracic transplantation is needed. This chapter will provide a background on the immune system and allorecognition. It will describe how the immune system mediates rejection of lung and heart transplants, types of organ rejection, and the histologic appearance of rejection. It

[1]The authors would like to acknowledge Norman Barker and Dr. Peter Illei for their help with the images in this chapter.

will further describe methods to monitor allograft rejection and the criteria upon which rejection is characterized. Finally, the chapter will cover basics of immunomodulation therapy.

## History of Primary Graft Failure and an Understanding of the Role of Allorecognition

Experimental heart transplantation developed slowly through the 1940s and 1950s, but became established in the laboratory of Dr. Norman Shumway by the mid-1960s. Human heart transplantation was first performed by Dr. Christian Bernard in 1967. Heart transplant outcomes were initially poor due to quick rejection of the organ. Experimental lung transplantation in mammals occurred throughout the first half of the 20th century. The first human lung transplantation occurred in 1963, although "successful" transplantation did not occur until the early 1980s. For both organs, early survivability was dependent on a number of factors, but key among them was an understanding and control of organ rejection. These early transplants failed because there was no effective way to control organ rejection without overly suppressing the immune system leading to fatal infections. The revolution in solid organ transplant was made possible by the immunosuppressive drug cyclosporine, discovered in the mid 1970s and introduced clinically in 1983. It prevented acute rejection of the organ, but allowed the body to ward off infectious agents. Thus successful organ transplantation is dependent upon a keen understanding of the interaction of the immune system with the transplanted organ. Our understanding of this interaction is focused on the role of the major histocompatibility complex (MHC) and the innate immune system in solid organ rejection.

## MAJOR HISTOCOMPATIBILITY COMPLEX

The MHC is one of the essential parts of the immunoregulatory process. The MHC genomic region encodes a large and diverse group of proteins that are expressed on all cells. These MHC proteins present antigen (polypeptide fragments of cell proteins) to immune cells, predominantly T cells. There are two major classes of MHC molecules. Class I molecules are found on all nucleated cells and present antigen to CD8 positive ($CD8^+$) "cytotoxic" T cells and natural killer (NK) cells. Class II MHC proteins occur on antigen presenting cells (APCs) and present antigen to CD4 positive ($CD4^+$) "helper" T cells. In the lung and heart, native dendritic cells are the primary MHC class II positive APCs.

## RECOGNIZING SELF AND DEVELOPING TOLERANCE

With all human cells constantly presenting antigen to T cells, one might wonder why our bodies are not under constant immunologic attack. The answer is that through our first year of life, our body learns to differentiate between self and nonself antigens. This process occurs primarily in the thymus in which an enormous diversity of T cells each displaying a different T-cell receptor complex interacts with thymic epithelial cells. Only those T cells that have an intermediate affinity for self-antigen MHC complexes (an ability to recognize, but not react) are allowed to survive. T cells with either no affinity or high affinity to self peptide MHC complexes are removed. Thus, after the first year of life, our T cells have developed the capability to perform immunosurveillance and differentiate between self and nonself antigens presented by MHC complexes.[1]

## ALLORECOGNITION PATHWAYS

APCs are the most potent initiators of alloimmune responses because they express high concentrations of both MHC class I and II antigens (Fig. 49-1). The MHC class II antigens are required to activate CD4 helper T cells. APCs also express numerous costimulatory molecules that provide secondary signals necessary for expansion of the T cells' response to the target antigens. APCs can participate in three pathways of allorecognition. All three pathways are involved in lung and heart rejection. The direct pathway is the mechanism by which recipient T cells recognize nonself antigen present on donor APCs. Transplants contain large numbers of donor APCs at the time of transplantation that are progressively replaced by recipient APCs. The indirect pathway occurs when necrotic or apoptotic cellular debris from donor cells are taken up by recipient APCs. These nonself antigens are then displayed via MHC class II molecules resulting in a $CD4^+$ cell-driven process. A third potential pathway is the semidirect pathway. Here, small cellular vesicles (exosomes) containing MHC move from a donor APC to a recipient APC and stimulate both $CD4^+$ and $CD8^+$ T cells.[2] In addition to the described T cell MHC interaction, a costimulatory event must occur to optimally activate the T-cell response. The best studied costimulation interaction is between the CD28 protein on the T cell and a B7 molecule (B7-1 and B7-2; CD 80 and 86, respectively) on the APC.[3] A new immunosuppressive agent, LEA29Y (belatacept), blocks this interaction, although it is not yet used in thoracic transplantation.

## Secondary Stimulation of T-cell Response

Once a T cell has become activated, a number of inflammatory pathways become upregulated. The pathways described here are all targeted by immunosuppressive drugs that will be covered later in this chapter. T-cell receptor activation by MHC activates calcineurin. Calcineurin, in turn, activates a transcription factor (NF-AT) which increases the production of interleukin-2 (IL-2) and additional cytokines (Fig. 49-1). Secreted IL-2 binds an IL-2 receptor (IL-2R) on the cell surface stimulating expansion of the local immune cell population (predominantly T cells). This cell proliferation is partly

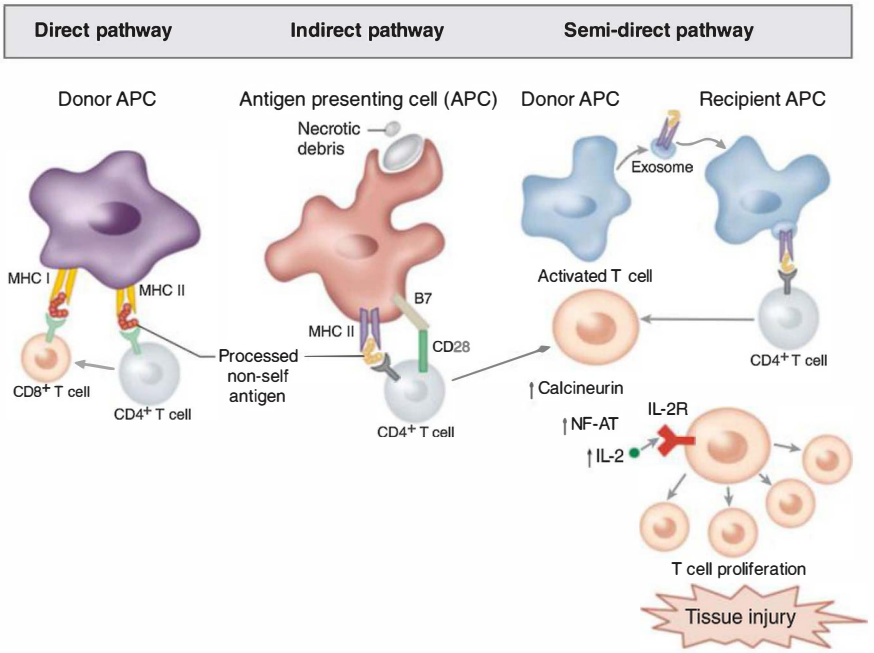

**FIGURE 49-1** Mechanisms of cellular rejection. In the direct pathway, all cells can express nonself antigens to T cells by MHC I molecules. In the indirect pathway, antigen presenting cells (APCs) (usually dendritic cells) phagocytize necrotic debris and present this to $CD4^+$ T cells via MHC II molecules. In the semidirect pathway, donor APCs release exosomes with MHC II molecules that are taken up by recipient APCs. These recipient APCs present nonself antigen to $CD4^+$ T cells. Stimulation of T cells by nonself antigen cause an increase in calcineurin, which increases the nuclear transcription factor NF-AT, which results in elevated IL-2. IL-2 acts in autocrine and paracrine fashion to stimulate local T-cell proliferation that causes tissue injury.

mediated by a direct stimulatory effect of IL-2R on mTOR which regulates the cell cycle.[3] The result of this activation pathway is increased inflammatory cells in the donor organ and injury seen as epithelial cell or myocyte death.

## INNATE IMMUNE SYSTEM

In distinction to the adaptive immune response that is defined by antigen specific receptors on lymphocytes (T cells and B cells), the innate immune system encompasses mediators and cells with invariant receptors (Table 49-1). These include proteins of the complement system as well as an array of cells, notably platelets, granulocytes, monocytes, and macrophages. Components of the innate immune system evolved to survive pathogens and tissue injury (Fig. 49-2). Toll-like receptors (TLR) and mannose binding lectin (MBL) are good examples of what Janeway[4] termed pattern recognition receptors that bind to pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs). PAMPs include structural motifs unique to prokaryotes, such as lipopolysaccharide (LPS), bacterial lipopeptides, flagellin, and unmethylated DNA. DAMPs are intracellular or cryptic molecules that are exposed by tissue disruption or produced by cells in response to stress. Among the best-defined DAMPs are heat shock proteins (HSP) and fragmented hyaluronan. Other DAMPs such as high-mobility group box 1 (HMGB1) and IL-33 are located in the nucleus of live cells and released by necrotic cells.

Toll receptors were discovered in fruit flies because genetically deficient flies had morphogenic defects and were susceptible to fungal infections. On the basis of sequence homologies more than 10 TLRs have been identified in mammals. In humans, TLR 1, 2, and 6 can form heterodimers and TLR4 forms homodimers on the surface of leukocytes and parenchymal cells where they bind signature PAMPs and DAMPs (Fig. 49-3). TLR4, for example, binds LPS and fragmented hyaluronan.[5] Other TLRs, such as TLR3, are located on intracellular endosomes and recognize viral and bacterial RNA or DNA. Cell surface TLRs signal through MyD88 to upregulate a group of proinflammatory cytokines, including TNFα, IL-1, IL-6, and IL-12 as well as the chemokines IL-8 and MCP-1 that attract neutrophils and monocytes. TLR4 also signals through TRIF as does the intracellular TLR3 to upregulate IFNα and β (Fig. 49-3).

MBL is integrated into the complement system of mammals as one of three initiators of the complement cascade. MBL is a member of the collectin family of proteins that are characterized by collagen-like tails with globular lectin heads, hence "col-lectin."[6] The lectin heads can bind to carbohydrates terminating in mannose, fucrose and N-acetylglucosamine (GlcNac) that typify bacteria. The

**TABLE 49-1: Examples of Pattern Recognition Receptors of the Innate Immune System that are Relevant to Transplantation**

| Pattern Recognition Receptor (PRR) | Location | Pathogen | Apoptotic/Necrotic or Stressed Cells |

[b]Membranes of intracellular compartments, for example, endosomes and lysosomes.

affinity of these reactions is low, but MBL forms oligomers of two, three, four, or six molecules that bind arrays of repeated carbohydrate motifs with relatively high avidity. Homologues of collectins and MBL have been identified in invertebrate animals such as sea squirts. These animals lack most of the remainder of complement components. Therefore, collectins arose as primitive pattern recognition molecules that opsonized bacteria for phagocytes. They also opsonize subcellular debris from injured or senescent cells for removal by phagocytes. In mammals, innate immunity functions both independently and in conjunction with the adaptive immune response.[7]

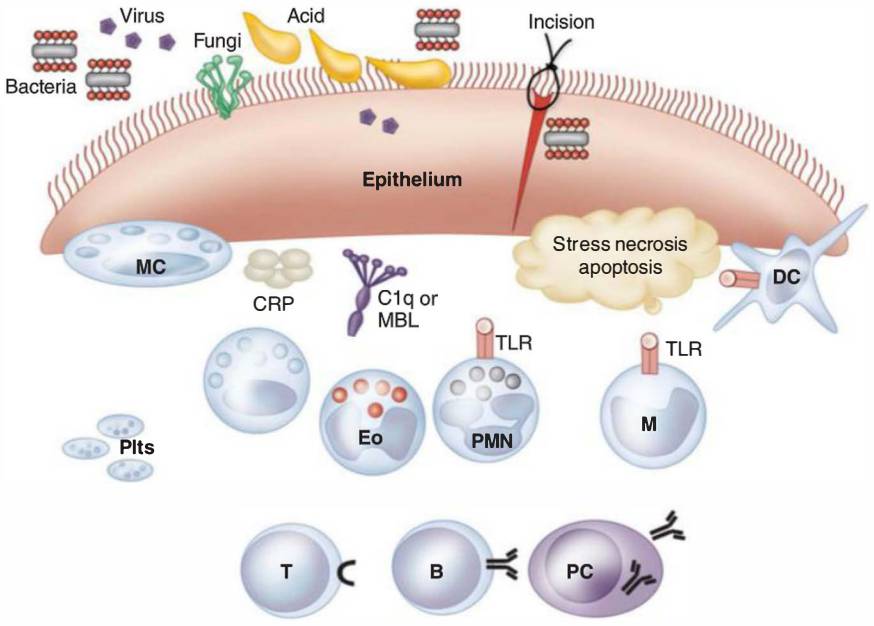

**FIGURE 49-2** Overview of the elements of the innate immune system. Most pathogens (fungi, bacteria, and viruses) are prevented from entrance to the body by chemical and physical barriers of skin and mucosal surfaces. The mucosal surface of the lung has the additional protection of cilia that move mucus along the surface. These barriers can be breached by toxic materials (e.g., gastric juices refluxed into the lung) or surgical incisions. These same insults can cause cells to undergo stress, apoptosis, or necrosis. Pathogens and damaged cells are recognized by soluble or cell-bound receptors of the innate immune system. These include C-reactive protein (CRP), complement components (C1q and MBL), and Toll-like receptors (TLR). Cells of the innate immune system, such as neutrophils (PMN), macrophages (M) and dendritic cells (DC), mast cells (MC), eosinophils (Eo), and platelets (plts), can react through TLRs and receptors for complement or cytokines. Innate immunity provides the immediate response that allows the cells of the adaptive immune system (T cells, B cells, and plasma cells) time to respond.

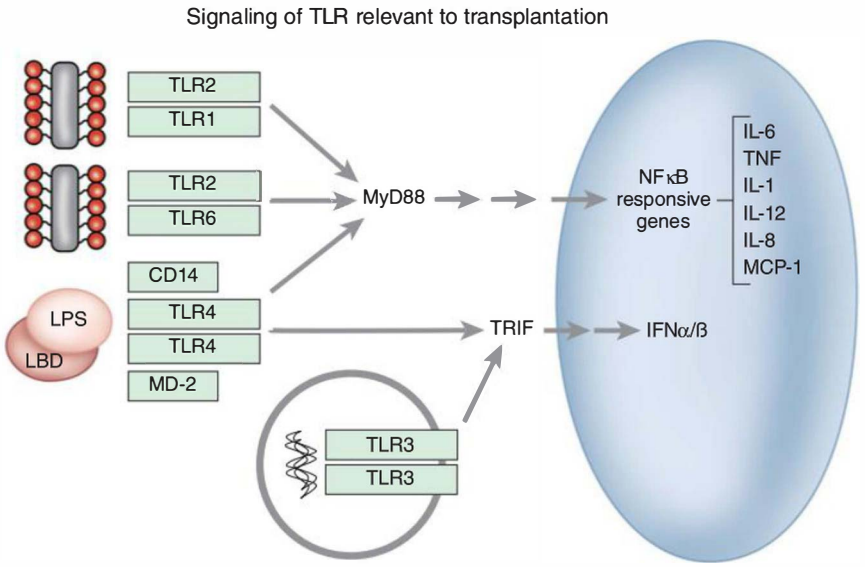

**FIGURE 49-3** Cytokine responses signaled by Toll-like receptors (TLR). TLR on the external cell membrane recognize cell wall components of bacteria and fungi. TLR in endosomal membranes recognize RNA or DNA from viruses and bacteria. Signaling pathways through MyD88 cause the upregulation of a group of nuclear factor kappa B responsive genes including those for the proinflammatory cytokines IL-6, TNFa, IL-1, IL-12, IL-8 and MCP-1). Signaling through the TRIF pathway causes upregulation of type I interferons (IFN).

## INNATE IMMUNE SYSTEM IN PERIOPERATIVE GRAFT INJURY

Unlike adaptive immune responses, which require days to generate, the invariant receptors of the innate immune system provide immediate responses in the postoperative period. Of particular relevance to transplantation are the innate immune responses to ischemia imposed by organ procurement followed by reperfusion when the transplant operation is completed (Table 49-2). Unmitigated ischemia–reperfusion injury is characterized by activation of the complement cascade, platelets, and granulocytes. The ensuing tissue injury results in macrophage infiltration. Even with current preservation solutions, which are designed to diminish this injury, early protocol biopsies often contain some evidence of ischemic injury histologically identifiable by macrophage infiltrates and deposits of complement split products (C4d and C3d) on damaged myocytes.

Organs from deceased donors are subject to multiple insults that can augment innate immune responses. These include sequella of traumatic injury, brain death, and various emergency interventions (Fig. 49-2). Surgical procedures cause tissue injury resulting in exposure of DAMPs and initiation of wound healing responses. In addition, incisions break mechanical and chemical barriers, providing portals for infectious agents and stimulation of innate immunity through PAMPs.

Thoracic organ transplants that require cardiopulmonary bypass have additional inciting stimuli for the innate immune system. These include the bioincompatible surfaces of the bypass equipment that cause complement activation. Any platelet transfusions also introduce partially activated platelets that release chemokines and cytokines. The inflammatory effects of the innate immune responses can be decreased by administration of steroids postoperatively.

## INTERACTIONS OF THE INNATE IMMUNE SYSTEM WITH ADAPTIVE IMMUNITY

Components of the innate immune system facilitate de novo adaptive immune responses and augment preexisting or ongoing adaptive immune responses. Macrophages in ischemic sites, for example, can upregulate MHC class II expression and present antigen to T cells. Preexisting or newly induced antibodies can activate complement and generate biologically active split products that chemoattract and activate neutrophils and macrophages. As a result, these are the most common leukocytes in antibody-mediated rejection (AMR). C5 is a pivotal component of complement because it is cleaved into two key split products when it is activated: C5a, which is a powerful chemoattractant and activator of neutrophils and macrophages; and C5b that initiates the formation of the membrane attack complex (C5b–C9) that can lyse endothelial cells. This has led to the development of therapeutic agents to block C5 including monoclonal antibodies to C5, small-molecule antagonists for C5a, and soluble receptors for C5a.

**TABLE 49-2: Stimulants to the Innate Immune System that are Relevant to Transplantation**

| Event | Donor | Recipient | Innate Responders |
|---|---|---|---|
| | | **Pretransplant** | |
| Fatality | Major trauma | | Platelet activation, etc. |
| Organ procurement | Organ ischemia | | Complement, neutrophils, platelets, macrophages |
| Pretransplant maintenance | | Dialysis, ventricular assist device | Complement, neutrophils, platelets, macrophages |
| Intraoperative procedures | | Surgery, cardiopulmonary bypass | Complement, neutrophils, platelets, macrophages |
| | | **Posttransplant** | |
| Postoperative | | Organ reperfusion | Complement, neutrophils, platelets, macrophages |
| | | Antibody-mediated rejection | Complement, neutrophils, platelets, macrophages |
| | | Cell-mediated rejection | Macrophages, platelets |
| | | Infectious complications to the lung | Complement, neutrophils, macrophages |

Cells of both the innate and adaptive immune systems express receptors for complement split products. Macrophages express receptors for C5a that stimulate the upregulation of receptors for other complement split products and for the $F_c$ of antibodies. Therefore, interactions of macrophages with C5a increase their responses to antibodies and complement. T cells also have receptors for C5a, and B cells have receptors for C3d, which increase their responses triggered by their antigen-specific receptors.

## ANTIBODY-MEDIATED IMMUNE RESPONSE

In addition to innate and T-cell–mediated immune responses, B cells also remain vigilant against transplanted tissues. Here, B cells make antibodies that target donor endothelium. These antibodies activate the complement cascade of innate immunity. As a result the long-lived split products of complements C3 and C4 (C3d and C4d) covalently bind to the endothelium. This AMR can occur immediately after transplantation or weeks to months to years later. Hyperacute rejection occurs within the first 24 h after transplantation and is generally dependent upon the presence of preexisting anti-human leukocyte antigen (anti-HLA) antibodies that coat the endothelium and activate complement. Complement then causes endothelial injury resulting in interstitial hemorrhage, microthrombosis, and often an influx of inflammatory cells. As a result of cross-matching for antibodies to HLA (see Chapter 11), hyperacute rejection rarely happens in heart and lung transplantation. More frequently, AMR occurs as the consequence of antibodies that are made after transplantation. AMR is increased in people with prior antigenic exposures including prior blood transfusions, child-bearing women, and the use of some mechanical support devices.[8,9]

## Chronic Lung Rejection

Chronic rejection is a terminal event for lung and heart transplants, for which there is currently no effective treatment. In the lung, chronic rejection is known as bronchiolitis obliterans syndrome (BOS). It is defined clinically by a decline in pulmonary function (reduction in forced expiratory volume in 1 s, FEV1, and/or forced midexpiratory flow rates, $FEF_{25-75}$). BOS is mediated by both immune- and nonimmune-mediated pathways. One of the known immunologic activations in BOS is the sensitization of $CD4^+$ T cells to MHC class I and class II molecules. Much of the resultant lung injury is from indirect pathway activation.[10] Antibodies directed at non-MHC antigens in the transplanted lung, such as antibodies to Kα1 tubulin or collagen V, may also induce injury and fibroproliferation.[11] Nonimmune contributors to BOS are the result of the lungs' interaction with the environment. Infections, stomach acid from gastrointestinal reflux disease (GERD), and primary graft dysfunction have also been implicated in BOS.[10]

## Chronic Heart Rejection

A diffuse concentric thickening of the coronary arteries termed coronary allograft vasculopathy (CAV) defines chronic heart rejection. Here, intimal smooth muscle proliferation causes narrowing of the coronary vessels to a point in which they can no longer supply the metabolic needs of the heart. As this is a diffuse process involving the entire coronary artery tree, unlike coronary atherosclerosis, there are no good options for stenting or using bypass grafts, making this a difficult to treat condition. Although still the target of much research, CAV is believed to be the sequella of injury to the vessel wall's endothelium. Sources of injury include immunologic (innate, T cell mediated, antibody mediated) and nonimmunologic (diabetes, obesity, hyperlipidemia,

hyperhomocysteinemia, and CMV) factors. The primary effector cell of injury is the macrophage. The macrophage secretes a variety of proinflammatory cytokines that cause tissue injury and promote smooth muscle cell proliferation in the intima.[12]

## Incidence of Rejection Events in Heart and Lung Transplantations

Over the past 20 years, a greater understanding of the immunologic response to donor organs has led to marked improvements in drugs and treatment regimens that delay graft failure, while minimizing complications of immune suppression such as renal toxicity, increased infections and elevated incidences of neoplasms. Despite that, acute rejection of both lungs and hearts still occurs with some frequency. The incidence of acute rejection occurring in the first year after lung transplantation is 36 percent.[13] For heart transplantation, ~25 percent of patients develop acute cellular rejection in the first year.[14] Most cardiac transplantation centers report AMR occurring in less than 10 percent of subjects.[15] Chronic pulmonary rejection (BOS/OB) is present in approximately 50 percent of lung transplant recipients at 5 years.[10] At 10 years, 90 percent of heart transplant recipients have developed CAV.[12]

## Histology of Pulmonary Rejection

Histology can differentiate between the acute and chronic processes that lead to pulmonary rejection. The acute processes in the lung affect the parenchyma (epithelial tissue), small blood vessels and airways. Acute rejection is noted by the presence of a mononuclear cell infiltrate in the parenchyma, a "cuffing" of the blood vessels, and pneumocyte damage (Fig. 49-4). Lymphocytic bronchiolitis is the process of rejection occurring in the airways. A working formulation for acute lung rejection has been created by the International Society of Heart and Lung Transplantation (ISHLT) (Table 49-3).[16] Chronic rejection of the lung is known as obliterative bronchiolitis and is the histologic equivalent of BOS described above. This obliterative process has a dense eosinophilic or myxoid hyaline fibrosis within the airways (Fig. 49-4).

## Histology of Cardiac Rejection

The three types of cardiac rejection (acute cellular, chronic and AMR) all have distinctive histologic appearances. Histologically, acute cellular rejection is defined by the infiltration of T cells within the myocardium and myocyte death. The extensiveness of the infiltrate and degree

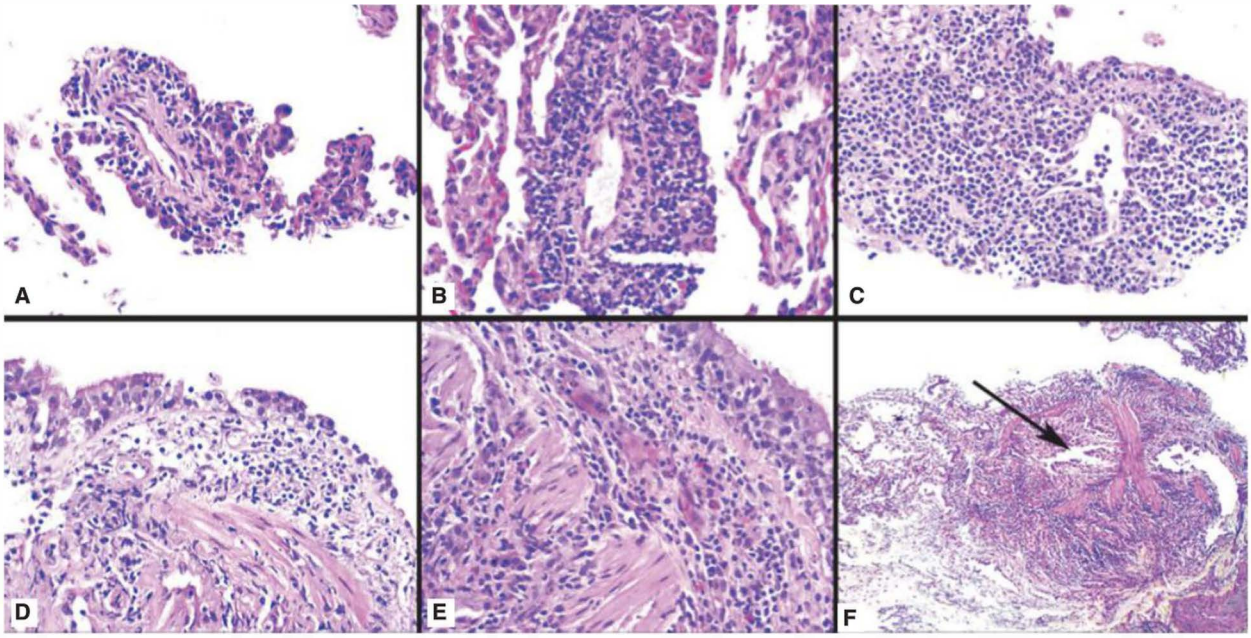

**FIGURE 49-4** Histologic findings of pulmonary rejection. **A.** Minimal (A1) parenchymal rejection showing vascular cuffing of mononuclear cells. **B.** Mild (A2) rejection showing enhanced perivascular mononuclear infiltrates without infiltration of the alveolar septa or airspaces. **C.** Moderate (A3) rejection with dense mononuclear cuffing of small blood vessels and extension of infiltrate into pervascular and peribronchioloar spaces. **D.** Low-grade (B1R) airway rejection showing a mononuclear infiltrate in the bronchiolar submucosa without epithelial damage. **E.** High grade (B2R) rejection has marked mononuclear infiltrate in the submucosa with plasmacytoid cells and eosinophils causing epithelial damage. **F.** Early bronchiolitis obliterans (C1) with fibrosis beginning to obliterate the airway resulting in luminal occlusion (arrow).

**TABLE 49-3: ISHLT Pulmonary Biopsy Grading Scheme for Acute and Chronic Rejection**

| Rejection Severity | Numerical Grade | Histologic Findings | Need to Increase Treatment? |
|---|---|---|---|
| | | **Parenchyma** | |
| None | A0 | Normal pulmonary parenchyma | No |
| Minimal | A1 | Scattered perivascular mononuclear infiltrates and vascular cuffing | Controversial |
| Mild | A2 | Frequent perivascular mononuclear infiltrates ± eosinophils ± endothelialitis, but without infiltration of the alveolar septa or air spaces | Controversial |
| Moderate | A3 | Dense mononuclear cell cuffing of small blood vessels, endothelialitis, common eosinophils, and extension of infiltrate into perivascular and peribronchiolar alveolar septa and airspaces | Yes |
| Severe | A4 | Diffuse mononuclear cell perivascular, interstitial, and air–space infiltrate and endothelialitis ± necrotic epithelial cells ± macrophages ± hyaline membranes ± hemorrhage ± neutrophils. | Yes |
| | | **Airway** | |
| None | B0 | No bronchiolar inflammation | No |
| Low grade | B1R | Mononuclear infiltrate in the submucosa without epithelial damage ± eosinophils | No? |
| High grade | B2R | Marked mononuclear infiltrate in the submucosa, eosinophils, plasmacytoid cells, epithelial damage (necrosis and metaplasia) | Yes |
| Ungradeable | BX | Not gradeable due to inadequate sample | No |
| | | **Chronic rejection** | |
| Absent | C0 | No bronchiolitis obliterans | |
| Present | C1 | Bronchiolitis obliterans | |

Data from Stewart S, Fishbein MC, Snell GI, et al. Revision of the 1996 working formulation for the standardization of nomenclature in the diagnosis of lung rejection. *J Heart Lung Transplant* 2007;26(12):1229–1242.

of myocyte injury are highly variable, but correlate with the severity of the rejection (Fig. 49-5). The ISHLT has a working formulation for diagnosing acute cellular rejection (Table 49-4).[17] Chronic rejection is also known as transplant vasculopathy or advanced graft arteriosclerosis (AGA). This is a process of diffuse intimal thickening throughout the coronary arterial tree. Histologically, there is a concentric proliferation of vascular smooth muscle cells in the intima. Perivascular inflammation including T cells, B cells, plasma cells, and macrophages is frequently observed. The diagnosis of AMR is not made by detecting specific antibodies in the tissue, but rather is made by positive staining for the complement split products C4d and C3d as described below.

## Tools to Monitor Pulmonary Rejection

The gold standard for determining acute cellular rejection in lung transplantation is the transbronchial lung biopsy (TBB) and bronchoalveolar lavage (BAL). A TBB is performed using a flexible bronchoscope and five or more pieces of alveolated tissue are collected. These tissues and the BAL are used to differentiate between infections and rejection. Although slightly controversial, surveillance TBB are performed at most centers throughout the first year post transplantation. A typical surveillance protocol may biopsy the lung at 2, 4, and 6 weeks, then 3, 6, 12, 18, and 24 months post transplantation.[18] Emergent reasons to perform TBB/BAL are a radiographic infiltrate, a >10 percent decline in $FEV_1$, or respiratory symptoms.

Using ISHLT criteria, pulmonary rejection is evaluated separately in the parenchyma and in the airway (Table 49-3).[16] Both a hematoxylin and eosin (H&E)-stained slide and a connective tissue stain to highlight fibrosis are evaluated on each case. Acute rejection is diagnosed as either none, minimal, mild, moderate, or severe. This is dependent on the degree of mononuclear infiltrate, and the presence of eosinophils, neutrophils, and pneumocyte damage (Fig. 49-4A). Airway rejection is evaluated only in small airways (bronchioles) and is determined based upon a lymphocytic infiltrate within the mucosa and, if severe, the submucosa as well (Fig. 49-4B). All acute rejection should be distinguished from an infectious infiltrate and correlated with clinical information.

Chronic airway changes are described as obliterative bronchiolitis and represent a terminal injury to the lung. Here, dense fibrosis obliterates the airways resulting in luminal occlusion. The fibrosis can be seen in concert with myxoid material, eosinophilic change, and chronic inflammatory cells (Fig. 49-4F).

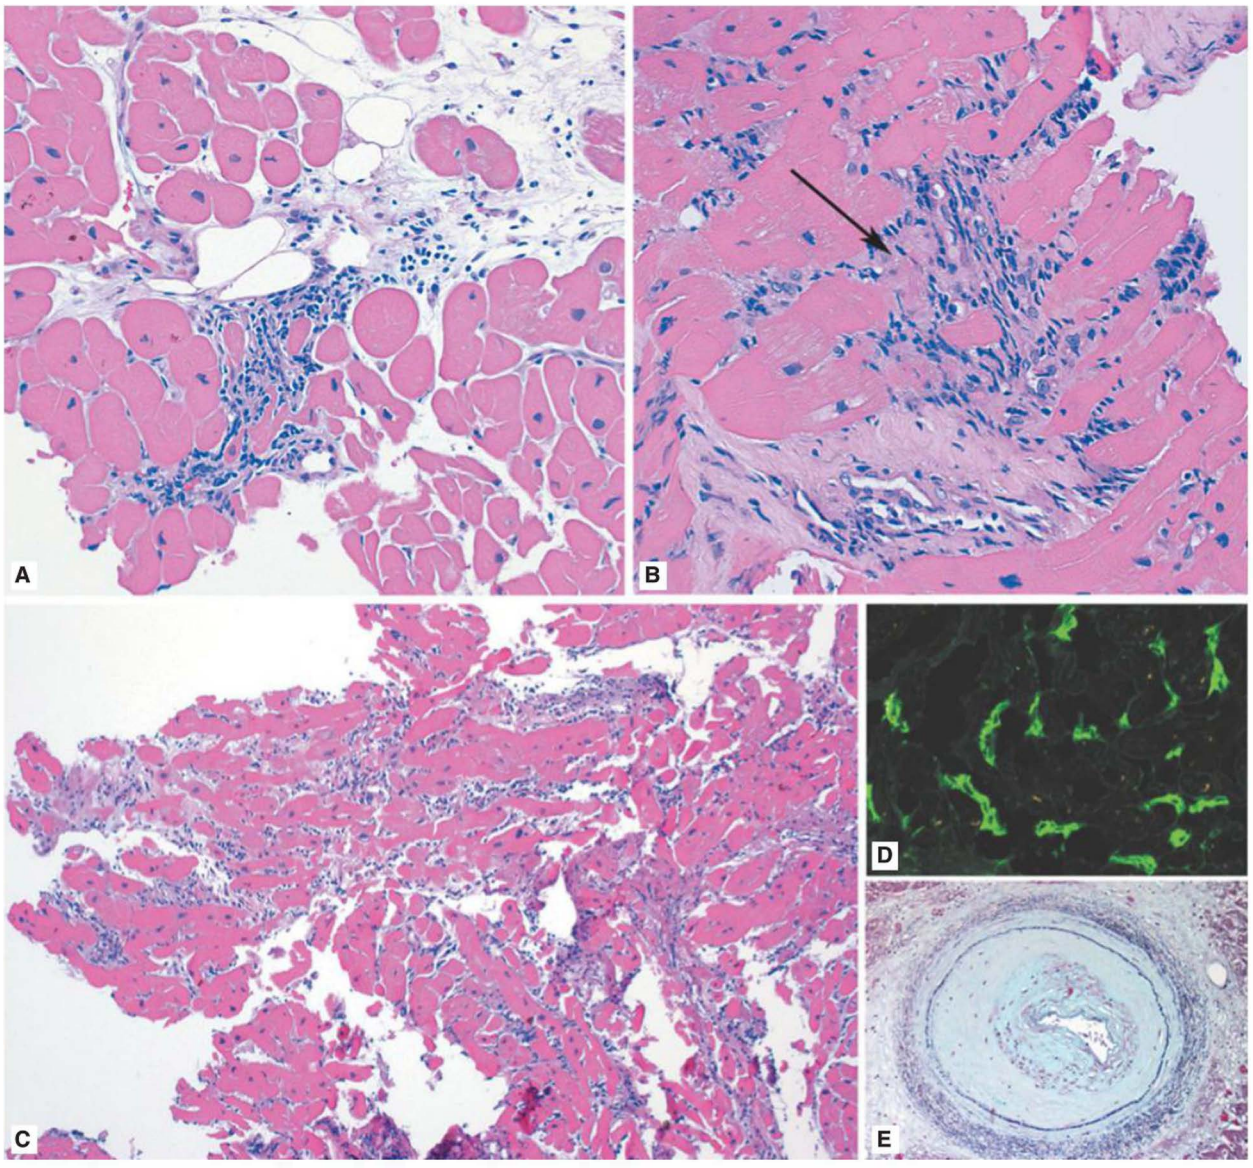

**FIGURE 49-5** Histologic findings of cardiac rejection on endomyocardial biopsy. **A.** Mild (1R) rejection showing perivascular and interstitial lymphocytes without myocyte injury. **B.** Moderate (2R) rejection showing a lymphocytic infiltrate in one of at least two distinct foci of myocyte injury (arrow). **C.** Severe (3R) rejection showing a marked lymphocytic infiltrate with diffuse, multifocal myocyte injury. **D.** AMR is present as noted by strong immunofluorescent staining of C4d in capillaries present between myocytes. **E.** Transplant vasculopathy showing concentric intimal proliferation (Movat Pentachrome).

## TOOLS TO MONITOR CARDIAC REJECTION

The gold standard for immune surveillance in the posttransplant setting remains the endomyocardial biopsy (EMBx). Newer, blood-based methods to monitor for a immunologic "fingerprint" of rejection have been tried, but have not, as yet, surpassed the sensitivity or specificity of direct tissue evaluation.[19] EMBx is performed by inserting a catheter-based Caves bioptome into the right ventricle by way of jugular vein access. Three or more pieces of myocardium are taken from the septum under radiographic guidance. This procedure is generally performed weekly for the first month, biweekly for the second month, monthly for 6 months, and bimonthly for the remainder of the first year. Biopsies are then continued on a yearly regimen or for clinical concerns.

**TABLE 49-4: ISHLT Cardiac Biopsy Grading Scheme for Acute Cellular and Antibody-Mediated Rejection**

| Rejection Severity | Numerical Grade | Histologic Findings | Need to Increase Treatment? |
|---|---|---|---|
| None | 0R | No inflammatory infiltrate | No |
| Mild | 1R | Mild interstitial and/or perivascular lymphocytic infiltrate and up to one focus of myocyte injury | No |
| Moderate | 2R | Moderate lymphocytic infiltrate ± eosinophils ± neutrophils and two or more foci of myocyte injury | Yes |
| Severe | 3R | Diffuse mixed inflammatory infiltrate with multifocal myocyte damage ± edema ± hemorrhage ± vasculitis | Yes |
| No AMR | AMR 0 | No capillary C4d staining | No |
| AMR | AMR 1 | Positive capillary C4d staining ± macrophage filling of small vascular spaces | Yes |

Data from Stewart S, Winters GL, Fishbein MC, et al. Revision of the 1990 working formulation for the standardization of nomenclature in the diagnosis of heart rejection. *J Heart Lung Transplant* 2005;24(11):1710–1720.

Most centers regard a proportional left ventricular ejection fraction decrease of ≥25 percent and/or other heart failure symptoms as reasons for emergent biopsy.

Acute cellular rejection is evaluated by light microscopy by a pathologist and the information is conveyed according to the ISHLT working formulation (Table 49-4).[17] If there is no infiltrate, the biopsy is said to have no rejection (0R). Mild rejection (1R) is the presence of a lymphocytic infiltrate of any degree in which there is only up to one focus with adjacent myocyte damage. Moderate rejection (2R) is the presence of a lymphocytic infiltrate and two or more foci of myocyte damage (Fig. 49-5). Severe rejection (3R) is a diffuse infiltrate with diffuse myocyte damage. In most centers, only moderate or severe rejection would result in additional immunosuppressive treatment.

AMR is evaluated by staining for the complement split product C4d and other stains including C3d. This staining can be detected by either immunohistochemistry or immunofluorescence and should be diffusely positive on capillary endothelium throughout the endocardium (Fig. 49-5). Other light microscopy findings are controversial, but the presence of macrophages filling capillaries or small venules is regarded as consistent with AMR. ISHLT guidelines indicate the presence of AMR is to be reported as AMR 1 and no AMR is to be reported as AMR 0.

Chronic cardiac rejection, CAV, is monitored by coronary angiography and the assessment of cardiac allograft function. A new scoring system has been developed to quantify the amount of CAV. The scores range between $CAV_0$ and $CAV_3$. $CAV_0$ (Not significant) denotes no detectable angiographic lesions. $CAV_1$ (Mild) indicates a lesion <50 percent of the left main coronary artery or either a primary vessel lesion or branch stenosis with narrowing of <70 percent combined with no allograft dysfunction. $CAV_2$ (Moderate) is used to indicate a ≥50 percent left main occlusion or either a single primary vessel or isolated branch stenosis in 2 systems of ≥70 percent without allograft dysfunction. $CAV_3$ (Severe) can be used to indicate both severe angiographic disease or symptomatic disease. Any $CAV_1$ or $CAV_2$ disease with allograft dysfunction (LVEF ≤45 percent) or restrictive physiology can be upscored to $CAV_3$. Also, $CAV_3$ is used when there is an angiographic lesion of the left main ≥50 percent or two or more primary vessels ≥70 percent or isolated branch stenosis ≥70 percent of all three systems.[20]

## Monitoring Donor-Specific Antibodies

In addition to immunosurveillance by evaluation of the inflammatory infiltrate in the heart and lungs, blood tests are performed to identify antibodies made by the recipient that may be directed toward the donor organ. Prior to transplant, these assays determine whether the potential recipient has been sensitized to nonself antigens through blood transfusions, prior surgeries, or pregnancies. This determination is made by evaluating the presence and titers of anti-HLA antibodies. If anti-HLA antibodies are present at high titer, desensitization protocols using plasmapheresis are used to lower these anti-HLA antibodies. After transplantation, the recipient may make antibodies directed at the donor organ resulting in AMR. These donor-specific antibodies (DSA) may be raised to a variety of nonself antigens on the heart, including endothelial proteins. At this time, however, our understanding of these nonself antibodies is incomplete and we can generally assess only anti-HLA antibodies. DSA are evaluated by solid-phase assays. State-of-the-art devices use fluorochrome-embedded beads attached to different HLA antigens. In these assays, recipient serum is tested against a full range of HLAs to determine if the recipient is making anti-HLA antibodies that may target the donor organ. Due to the conformational similarity between many HLAs, cross-reactions such as HLA B27 to HLA B2 may also trigger an AMR event.

## DRUG THERAPY FOR ACUTE REJECTION IN HEART TRANSPLANTATION

The immunosuppressive regimens used to suppress cardiac rejection generally fall into three categories: "induction," "maintenance," and "rejection" (Table 49-5).[21,22] While protocols are usually similar between centers for "maintenance" and "rejection," this is not true for "induction" protocols. An "induction" regimen begins at the time of transplantation. This regimen varies widely by both institution and patient characteristics. Some institutions perform this on all heart recipients. Others are selective. A common reason to perform "induction" therapy is to spare the kidneys

**TABLE 49-5: Antirejection Drugs**

| Drug Name | Effect | Major Side Effects | Used for |
|---|---|---|---|
| | | **Calcineurin inhibitor** | |
| Cyclosporin A | Blocks calcineurin and IL-2 activation | **Nephrotoxicity**, hypertension, hypercholesterolemia, hypertrichosis, gingival hypertrophy | Heart and lung maintenance (less favored) |
| Tacrolimus | Blocks calcineurin and IL-2 activation | **Nephrotoxicity**, hypertension, diabetes mellitus, neurotoxicity | Heart and lung maintenance (favored) |
| | | **Corticosteroid** | |
| Prednisone, Prednisolone, Methylprednisone | Suppress prostaglandin synthesis, reduce histamine/bradykinin release, downregulate cytokines | **Impaired glucose tolerance, bone density loss**, acne, hirsutism, Cushingoid features | Heart and lung maintenance and acute rejection (often tapered away in heart) |
| | | **Monoclonal antibodies to leukocytes** | |
| Basiliximab | Anti-CD25 (IL-2R) antibody, inhibits T-cell proliferation | | Heart and lung induction |
| Alemtuzumab | Anti-CD52 antibody | | Heart and lung induction (less favored) |
| Rituximab | Anti-CD20 antibody, depletes B cells | | Heart AMR |
| | | **Cell-cycle inhibitor** | |
| Azathioprine | Inhibits purine biosynthesis and lymphocyte proliferation | Leucopenia, malignancy | Heart and lung maintenance (less favored) |
| Mycophenolate mofetil (MMF) | Inhibits purine biosynthesis and lymphocyte proliferation | Diarrhea, leucopenia | Heart and lung maintenance (favored) |
| | | **Antithymocyte globulin (ATG)** | |
| Polyclonal anti-lymphocyte preparation (ATGAM) | T-cell cytotoxic | **Cytokine release syndrome**, leucopenia, thrombopenia, allergic reaction, infections | Heart induction |
| Anti-thymocyte globulin (Thymoglobulin) | T-cell cytotoxic | Infections, thrombopenia | Heart induction and acute rejection (less favored) |
| | | **mTOR inhibitor** | |
| Sirolimus | Prevents T-cell proliferation | **Hyperlipidemia**, delayed wound healing, pneumonitis, thrombocytopenia, arthralgia | Some use in replacing calcineurin inhibitors/ may delay CAV and BOS |
| Everolimus | Prevents T-cell proliferation | **Hyperlipidemia**, delayed wound healing, thrombocytopenia, arthralgia | Some use in replacing calcineurin inhibitors/ may delay CAV and BOS |
| Muromonab-CD3 (OKT3) | Blocks T-cell binding to APCs | **Cytokine release syndrome**, lymphoproliferative disorders, induction of AMR, procoagulation effect | Lung induction (less favored) |
| | | **Immunoglobulin** | |
| Intravenous immunoglobulin (IVIg) | Interferes with $F_c$ receptors in reticuloendothelial system | | Heart AMR |

Data collected from Korom S, Boehler A, Weder W. Immunosuppressive therapy in lung transplantation: State of the art. *Eur J Cardiothorac Surg* 2009;35(6):1045–1055. Hunt SA, Haddad F. The changing face of heart transplantation. *J Am Coll Cardiol* 2008;52(8):587–598. Knoop C, Haverich A, Fischer S. Immunosuppressive therapy after human lung transplantation. *Eur Respir J* 2004;23(1):159–171.

from calcineurin inhibitors especially in patients with diabetes or any level of renal dysfunction. Other populations that more frequently have "induction" therapy are young females, presensitized patients, ventricular assist device recipients, and individuals with prior open chest surgery. The purpose of this regimen is to markedly suppress early cardiac rejection and try to increase tolerance of the new organ. This regimen is comprised of IL-2R antagonists or drugs that kill lymphocytes (ATGAM or thymoglobulin).

A "maintenance" regimen then follows the "induction" regimen and is designed to balance the need for continued immunosuppression to maintain graft function, while limiting the risk of infections and neoplasm. This therapy is comprised of a calcineurin inhibitor, an antiproliferative agent and a steroid that is generally tapered away. Patients who have evidence of cellular rejection by EMBx will undergo a short course of a "rejection" regimen that will further suppress them beyond their normal "maintenance" regimen. The change in medications is dependent upon the severity of the rejection and can be as minimal as a course of corticosteroids, increased doses of current medications, or an addition of an antilymphocyte agent.

## THERAPY FOR ANTIBODY-MEDIATED REJECTION IN HEART TRANSPLANTATION

Traditional immunosuppressive therapy is generally not effective in treating AMR. Patients diagnosed with AMR based upon positive C4d, DSA, and clinical symptoms have therapies targeted toward reducing antibodies and depleting B cells. These include plasmapheresis to eliminate circulating antibodies, intravenous immunoglobulins (IVIg) to inhibit residual antibodies, and possibly rituximab to deplete the B-cell population (Table 49-5). Due to the limited experience with AMR at most centers, treatments may vary widely between centers.

## DRUG THERAPY FOR ACUTE REJECTION IN LUNG TRANSPLANTATION

Similar to cardiac transplantation, immunotherapies for lung transplantation also can be considered "induction," "maintenance," and "rejection" (Table 49-5). Due to the overall fewer numbers of lung transplants that are performed relative to heart transplantations, consensus has not been reached on treatment regimens. Induction therapy is reported to occur in >50 percent of lung recipients.[13] A variety of therapies are used including ATGAM, tacrolimus, alemtuzumab, basiliximab, and daclizumab, with the last two being the most commonly used. For maintenance, three drug classes are commonly used: a calcineurin inhibitor, a cell-cycle inhibitor and steroids. The specific drug from each class along with relative dosing is variable among institutions. Unlike heart transplantation, steroid withdrawal is not widely performed. For acute rejection, intravenous corticosteroid pulses for 3 to 5 days and a temporary increase in dosing levels of the maintenance regimen are used.[23]

## SPECIAL CONSIDERATIONS

### ABO Incompatible Heart Transplantation

Due to a shortage of donors in the pediatric population, the use of ABO incompatible heart transplantation has been developed. A window of opportunity occurs in the first 6 months of life before "natural antibodies" to blood group A or B are generated due to cross-reactive carbohydrates on normal gut flora. This accounts for the lack of hyperacute rejection. The unanticipated finding has been the apparent establishment of tolerance to blood group antigens by the presence of the transplanted heart. For example, a patient of blood group O, who receives a blood group A heart develops antibodies to blood group B, but not to A.[24] Ten years of registry data indicates that survival of ABO incompatible heart transplant patients is comparable to ABO matched recipients, suggesting good long-term outcomes of this procedure.[25] ABO incompatible heart transplants have been reported in a few adults who have low titers of isohemagglutinins.[26]

### Combined Heart and Lung Transplantation

Some patients develop both heart and lung failure and need replacement of both organs. The primary causes are congenital heart disease, primary pulmonary hypertension, cystic fibrosis, and other rare and miscellaneous disorders. The immunosuppression protocols for lung transplantation are typically followed in these patients. Rejection occurs almost exclusively in the lungs of these individuals, and not surprisingly, pulmonary complications are more prevalent than cardiac complications for these individuals and are a more likely cause of mortality.[13]

## THE IMMUNOBIOLOGY OF THORACIC TRANSPLANTATION BOARD REVIEW QUESTIONS (CHAPTER 49)

1. Which is true regarding the mechanism of indirect allorecognition pathway?
   A. MHC class I and II molecules on donor APCs present nonself antigen to $CD4^+$ T cells.
   B. Necrotic nonself cellular debris is phagocytized by APCs, which display the nonself antigen through MHC class II molecules for $CD4^+$ T cells.
   C. Exosomes containing MHC move from donor APCs to recipient APCs, which display nonself antigen to $CD4^+$ T cells.
   D. Necrotic transplanted cells become coated in complement, which activates macrophages.
   E. Bacterial infections in the transplanted organ activate TLR on neutrophils, which initiate signaling activating a T-cell response.

2. Which of the following is not a pattern recognition receptor of the innate immune system?
   A. CRP
   B. MBL
   C. Cyclooxygenase 1 (COX1)
   D. Complement C1q
   E. TLR1

3. What is the most appropriate therapy for a lung transplant biopsy graded as parenchymal moderate rejection (A3) with no bronchiolar inflammation (B0)?
   A. No treatment
   B. Two-week course of ATGAM
   C. Intravenous corticosteroid pulse
   D. IVIg with or without rituximab
   E. Basiliximab (anti-CD25 antibody) treatment

4. What is most appropriate therapy for a heart transplant biopsy graded as mild (1R) with no evidence of antibody mediated rejection (AMR0)?
   A. No treatment
   B. Two-week course of ATGAM
   C. Intravenous corticosteroid pulse
   D. IVIg with or without rituximab
   E. Basiliximab (anti-CD25 antibody) treatment

5. Which of the following is characteristic of moderate or severe cardiac rejection?
   A. Multiple foci of myocyte injury
   B. Positive staining for complement C4d
   C. Heavy infiltrate of lymphocytes interdigitating between myocytes
   D. Macrophages filling arterioles and capillaries
   E. Plugging of small blood vessels with thrombin

## ANSWERS

1. **Answer: B.** The indirect pathway involves necrotic nonself cellular debris that is phagocytized by APCs, which display the nonself antigen through MHC class II molecules for $CD4^+$ T cells. The direct pathway involves MHC class I and II molecules on donor antigen presenting cells (APCs) that present nonself antigen to $CD4^+$ T cells. The semidirect pathway requires exosomes containing MHC to move from donor APCs to recipient APCs, which display nonself antigen to $CD4^+$ T cells. Complement and bacterial infections do not contribute to the allorecognition pathways.
2. **Answer: C.** COX1 is not a pattern recognition receptor. CRP, MBL, C1q, and TLR1 are all part of the innate immune system.
3. **Answer: C.** A lung transplant recipient with moderate rejection on biopsy should be treated with steroid pulse therapy. No or mild rejection can be observed closely without increasing therapy. Antibody therapy is typically reserved for more severe forms of rejection.
4. **Answer: A.** Mild (1R) rejection on endocardial biopsy can be treated conservatively with no additional therapy. Moderate rejection is generally treated with steroid therapy, while more severe forms of rejection are treated with antibody therapies.
5. **Answer: A.** The presence of multiple foci of myocyte injury is diagnostic of moderate or severe rejection when compared with no or mild rejection. Complement staining is used to differentiate between AMR0 and AMR1. Lymphocyte infiltration, macrophage presence, and thrombin plugging are not specific to moderate or severe rejection.

# 50 Cardiac Transplantation

*Sara J. Shumway*

**KEY CONCEPTS**

- Epidemiology
  - Heart failure increases as the population ages and becomes increasingly obese. It can be acute or chronic, and systolic or diastolic.
- Pathophysiology
  - Heart failure may result from untreated hypertension or a myocardial infarction. Viruses may have caused idiopathic dilated cardiomyopathies. Hypertrophic cardiomyopathy is less common. Infiltrating cardiomyopathies also occur.
- Clinical features
  - Left-heart failure is manifested by shortness of breath, cough, and fatigue. Right-heart failure is responsible for right upper quadrant abdominal discomfort from a congested liver and peripheral edema. Ascites occurs later.
- Diagnostics
  - Patient with heart failure are evaluated by echocardiography, and right and left cardiac catheterization. Coronary angiography is still the gold standard for evaluating coronary artery disease.
- Treatment (medical/surgical)
  - Heart transplantation is reserved for patients who are failing medical management and are not thought to have a life expectancy of greater than 2 years. It can be done after the patient has been bridged with a left ventricular assist device (LVAD).
- Outcomes/prognosis
  - The median survival after cardiac transplantation is 10 years. The mortality rate after 1 year is 3 to 4 percent/year.

Theodore Billroth could never have imagined that one day cardiac transplantation would be a viable clinical entity. First, surgical techniques needed to be developed. The operation had to be reproducible. Myocardial protection was crucial. The heart was not so important to the organism that the organism would not reject it.[1] Over the course of the 20th century cardiac transplantation evolved from an experimental heterotopic model, where a puppy heart was placed in the neck of an adult mongrel dog, to an orthotopic operation where over 4400 heart transplants were performed in 1994.[2] Unfortunately, the number of donor hearts are not such that everyone with end-stage heart failure can be treated with transplantation. This has given rise to the evolution of mechanical circulatory assist devices that can be placed in patients to at least postpone cardiac transplantation.

Since cardiac transplantation became a clinical entity on December 3, 1967, well over 89,000 heart transplants have been performed.[3] Records have been collected by the International Society for Heart and Lung Transplantation in the form of a Scientific Registry since 1983. It has been interesting to watch the field evolve over the past 46 years. Over that course of time, decreased lengths of stay and increased ages of the donor and recipient have been realized.[4] Recipient waiting list times have increased dramatically, as have times before first rejection episodes.

## HISTORICAL BACKGROUND

Alexis Carrel and Charles Guthrie performed the first documented cardiac transplant in 1905 at the University of Chicago. The heart of a small dog was transplanted into the neck of an adult mongrel dog. Mann performed a heterotopic cardiac transplant in 1933.[5] A canine heart was sewn into the carotid-jugular circulation. The explanted heart revealed dense infiltration of the heart by lymphocytes, large mononuclear cells, and polymorphonuclear cells. It was cellular rejection.

By the late 1950s, experimental cardiac transplantation, both autografts and homografts, were being performed in the laboratory at Stanford. Using local hypothermia, orthotopic transplantation in dogs was successfully performed

in 1959. Richard Lower reported successful experiments in cardiac transplantation at the 1960 Surgical Forum of the American College of Surgeons.[6] By 1965, long-term survival of orthotopic cardiac transplantation was achievable in dogs. Electrocardiography was used to guide treatment of rejection. In the laboratory, using local and systemic hypothermia for myocardial protection, successful transplantation of the canine heart was achievable after 7 h of ischemia.

James Hardy transplanted a chimpanzee heart into a human as a desperate measure in 1964. Christiaan Barnard performed the first human-to-human heart transplant in Cape Town, South Africa, on December 3, 1967. The first cardiac transplant at Stanford University was performed on January 6, 1968. A number of programs throughout the world subsequently performed cardiac transplants between 1967 and the early 1970s with relatively poor outcomes; 5-year survival rates hovered around 40 percent. By the early 1970s Stanford and the Medical College of Virginia were the only two programs still actively conducting clinical cardiac transplant programs, with Stanford taking the lead in conducting basic and clinical transplant research. In 1971 Philip Caves, a British American research fellow, along with Margaret E. Billingham, developed a technique for the interpretation of percutaneous transvenous endomyocardial biopsies.[7] This important advance provided clinicians with the ability to better identify and treat cardiac allograft rejection.

By December 1980, the immunosuppressant cyclosporine was introduced into clinical use. By 1984, cyclosporine, corticosteroids, and azathioprine were combined as "triple drug therapy." This proved to be an effective immunosuppression regimen that was adopted widely.[8] Cardiac transplantation in children began in 1984.[9] By the 1990s, it was clear that induction therapy could be added to triple drug therapy in order to delay early acute rejection.[10] Chronic allograft rejection, manifested primarily as graft atherosclerosis, became the bête-noire of clinical cardiac transplantation.

The mid 1990s also saw the evolution of medical devices directed toward the treatment of heart failure, specifically ventricular assist devices and more reliable pacemakers and automatic implantable defibrillators. Over the past 20 years, ventricular assist devices have developed into effective bridges to transplantation or so-called "destination therapy" for end-stage heart failure.

## RECIPIENT SELECTION

The potential cardiac transplant recipient must undergo a battery of tests to determine whether or not he or she is an appropriate transplant candidate. Initially, a thorough history and physical examination, standard laboratory tests, plain chest radiography, and pulmonary function tests are obtained. Cardiac function is evaluated by electrocardiography, echocardiography, right and left heart catheterization, endomyocardial biopsy, and peak exercise oxygen consumption measurements.

**TABLE 50-1: Relative Contraindications for Cardiac Transplantation**

| |
|---|
| Age (70) |
| Active myocarditis |
| Graft failure due to acute rejection |

Screening tests include: stool guaiac, mammography for women, prostate-specific antigen screening for men, Papanicolaou smear for women, bone densitometry, and a carotid duplex study. Occult infectious diseases are ruled out with serologies for hepatitis B and C, HIV, HTLV1, and HTLV2, cytomegalovirus, Toxoplasma, Epstein–Barr virus, syphilis, and tuberculosis. Pretransplant data also includes blood type and antibody screening, HLA–DR typing, panel reactive antibody (PRA) screening, and a 12-h urine collection to measure creatinine clearance and total protein.[11]

Idiopathic and ischemic cardiomyopathies each comprise about 45 percent of the diagnoses among adult cardiac transplant recipients. The remaining diagnoses consist of valvular and congenital disease. Most recipients present in New York Heart Association class III or class IV heart failure refractory to medical therapy. Some patients suffer from intractable ischemia that is not amenable to catheter intervention or surgical revascularization. Still other patients present with intractable ventricular arrhythmias refractory to conventional therapies.

There have been recent advances in medical therapies for heart failure. In 2001, the COPERICUS trial found that patients with severe heart failure treated with Carvedilol had a reduced 1-year mortality of 11 percent compared with the placebo group who had a 1-year mortality of 19 percent. Waiting list mortality has decreased from about 32 to 17 percent due to the expanded use of ventricular assist devices and earlier consideration for cardiac transplantation.

There are relative, temporary, and absolute contraindications to cardiac transplantation (Tables 50-1–50-3). Severe pulmonary hypertension with pulmonary vascular resistances in excess of 4 Wood units or transpulmonary gradients greater than 15 mm Hg can lead to acute right ventricular failure of the newly implanted donor heart. Irreversible renal or hepatic dysfunction represent absolute contraindications to cardiac transplantation, although multiorgan transplants (e.g., heart–kidney, heart–liver) have been performed with some success.[12,13]

**TABLE 50-2: Temporary Contraindications for Cardiac Transplantation**

| |
|---|
| Active infection |
| Active peptic ulcer disease |
| Diverticulitis |
| Recent pulmonary/cerebral emboli |
| Symptomatic cholelithiasis |

**TABLE 50-3: Absolute Contraindications for Cardiac Transplantation**

| |
|---|
| Positive prospective crossmatch |
| Irreversible pulmonary hypertension (PVR ≥5 Wood units) |
| Malignancy |
| Severe peripheral or cerebral vascular disease |
| Irreversible renal dysfunction (creatinine clearance <40 mL/min) |
| Irreversible hepatic dysfunction |
| Severe obstructive or restrictive lung disease |
| Coexisting systemic disease |
| Diabetes mellitus with end-organ damage |
| Morbid obesity (≥30% predicted ideal weight) or BMI greater than 35 |
| Severe cachexia |
| Ongoing tobacco use or drug addition |
| Ongoing alcohol abuse |
| Noncompliance with medications |
| Inability to fully understand procedure and participate in follow-up care |

All potential recipients are screened for occult malignancy. Severe peripheral vascular disease and diabetes resulting in end-stage organ damage are also contraindications. Primary diseases of the heart such as amyloidosis or sarcoidosis and giant cell myocarditis can be contraindications. Relative contraindications to transplantation include age greater than 70 years, obesity greater than 140 percent ideal body weight, severe osteoporosis, a history of substance abuse, and psychiatric disorder. A history of medical noncompliance and lack of social support are other potential contraindications.

Once a patient has been listed for transplantation, he or she should be followed by a cardiologist at the transplant center, usually every 3 months. Cardiac rehabilitation is also an important tool during this waiting time. Patients suffering from severe heart failure may require intravenous inotropic support (e.g., dobutamine). Milrinone, a phosphodiesterase inhibitor with inotropic and vasodilatory affects, is also an effective inotrope, especially for right heart failure.

A number of devices have been used as adjuncts to medical therapy. Intra-aortic balloon pumps have provided circulatory support for as long as 2 to 3 weeks prior to heart transplantation. This appears to be most effective in patients with ischemic cardiomyopathies. For patients with severe refractory ventricular failure, a left ventricular assist device (LVAD) or right ventricular assist device may be necessary. INTERMACS is a database recently developed to track all patients requiring ventricular assist devices.[14]

The REMATCH trial, published in 2001, compared 1- and 2-year survival rates of heart failure patients who were not candidates for cardiac transplantation and were treated with either medical therapy or LVAD implantation.[15] The investigators reported a 25-percent 1-year survival rate and 8-percent 2-year survival rates in the medical therapy group compared with a 52-percent 1-year survival rate and a 23-percent 2-year survival rate in the LVAD group. The use of ventricular assist devices for bridging to transplantation is increasing.

## DONOR MANAGEMENT AND SELECTION

As with any organ donor assessment, the two most important goals are to prevent disease transmission from the donor to the recipient and to obtain a graft that will function appropriately. Donor heart exclusion criteria include (1) malignancy with extracranial metastatic potential, (2) systemic sepsis or endocarditis, (3) significant coronary artery disease, (4) anatomic heart disease that will shorten the recipient's expected life span, and (5) poor ventricular function.

Ideally, the cardiac donor is less than 55 years of age with no history of chest trauma or cardiac disease. There should be no prolonged hypotension or hypoxemia. Hemodynamically, the mean arterial blood pressure should be maintained above 60 mm Hg and the CVP between 8 and 12 mm Hg. Inotropic support requirements should be less than 10 mg/kg/min of dopamine or dobutamine. Normal electrocardiograms and echocardiograms should be verified. Risk factors for coronary artery disease mandate normal coronary angiography. All pertinent serologies should be negative.

Due to the relative donor organ shortage, there has been a trend toward liberalizing certain donor selection criteria. Expanded organ criteria include the use of older donors and allowing for longer ischemic times. Donors with mild left ventricular hypertrophy, mild valvular abnormalities, or mild coronary artery disease have been used with success.[16] Hearts that have experienced cardiac arrest have also been used.

Most organ donors who have suffered acute brain injury will display some hemodynamic instability. Neurogenic shock can cause excessive fluid losses and bradycardia. Careful fluid management is necessary. It is also important to wean inotropic support as much as possible. Blood transfusion is also used sparingly to maintain a hematocrit of at least 30 percent. If possible, cytomegalovirus negative and leukocyte-filtered blood should be used. Donors may require intravenous vasopressin to keep up with the excessive urine losses caused by diabetes insipidus.

A single echocardiogram may show decreased ventricular function related to brain death, so serial echocardiograms may show functional recovery. The Papworth group has instituted a very aggressive protocol for donor management.[17] Using pulmonary arterial catheter monitoring, donors are managed by a cardiac trained anesthetist. Hormonal therapy includes the use of thyroxine, cortisol, antidiuretic hormone, and insulin. If a left ventricular ejection fraction of greater than 45 percent is attained, the organ should be usable.

In the United States, organ allocation is governed by the United Network for Organ Sharing (UNOS). Heart allocation takes into consideration medical urgency, time on the waiting list, and blood type. The medical urgency categories

**TABLE 50-4: UNOS Medical Urgency Status Categories**

| Status Level | Category |
|---|---|
| 1A | Patient is listed at the transplant hospital and has one of the following devices or conditions:<br>1. Left and/or right ventricular assist device<br>2. Total artificial heart<br>3. Intra-aortic balloon pump<br>4. Extracorporeal membrane oxygenation<br>5. Mechanical circulatory support with evidence of significant device-related complications<br>6. Mechanical ventilation<br>7. Continuous infusion of a single high-dose intravenous inotrope.<br>8. Life expectancy <7 days |
| 1B | One of the following devices or conditions:<br>1. Left or right ventricular assist device<br>2. Continuous infusion of intravenous inotropes |
| 2 | All other actively listed patients |
| 7 | Patient is temporarily removed from active waiting list |

include status 1A, 1B, 2 and 7 (Table 50-4). The allocation algorithm is also modified by age so that adolescent donor hearts are preferentially used by pediatric recipients. Organs are initially allocated locally, then regionally.

Prospective recipients and donors must be ABO blood type compatible, except in infants. As far as size is concerned, typical acceptable donor weight ranges are between 70 and 130 percent of the recipient weight.[18] For recipients with moderately elevated pulmonary vascular resistance, it is often prudent to use a larger donor. Using smaller hearts in a heterotopic position for larger recipients has fallen out of favor. The donor team should have a checklist to ensure completeness of the donor organ assessment (Table 50-5).

There are certain strategies that have been used to improve preservation of the heart during organ retrieval. This has included the use of hypothermia, cardioplegia, and various preservation solutions. The heart is maintained in a hypothermic environment between 4°C and 8°C to reduce the rate of myocardial metabolism. Cardioplegia is used to arrest the heart. Adequate decompression of the ventricles during the organ retrieval limits injury to the heart during the actual procurement. The heart is stored in either cold saline or a variety of preservation solutions. Most preservation solutions were designed for perfusion or storage of abdominal organs.[19] Many also contain antioxidant additives to help prevent reperfusion injury. Cardiac preservation is usually limited to 4 to 6 h of cold ischemia time. Longer ischemia times have affected recipient survival. This is an area of active research.

**TABLE 50-5: Checklist for Donor Procurement Team**

## OPERATIVE TECHNIQUES

### Cardiac Allograft Procurement

Donor cardiac procurement is performed through a complete median sternotomy. The pericardium is opened widely and the edges are suspended. Care is taken not to enter either pleural space should the lungs be infected. The heart is inspected for any signs of trauma, infection, or congenital anomalies. Overall contractility of both the right and left ventricles is appreciated. The coronary arteries are palpated to rule out any evidence of coronary artery disease. The ascending aorta is separated from the pulmonary artery. The superior vena cava (SVC) is mobilized circumferentially up to and beyond the level of the azygos vein, and encircled with two heavy ties of 0 silk sutures. The inferior vena cava likewise is mobilized circumferentially and surrounded with a vessel loop.

At least 300 units of heparin/kg of donor weight are administered intravenously to the donor. A cardioplegia needle is inserted into the ascending aorta. Venous return to the heart is interrupted by dividing the SVC between two secured ties. The IVC is divided flush with the diaphragm. The tip of the left atrial appendage is amputated. The ascending aorta is cross-clamped and approximately 2 L of cold cardioplegia is administered into the ascending aorta. In children, 50 mL/kg of cardioplegia is appropriate. Ice slush is immediately poured into the pericardial space and onto the heart to provide rapid topical cooling. Once a complete cardiac arrest is achieved and all of the cardioplegia has been administered, the topical ice slush is removed from the pericardial space and the heart is excised in a expedient fashion. First, the pulmonary veins are divided flush with the pericardium. The aorta is divided as distally as possible, usually at the take off of the innominate artery, and the main pulmonary artery is divided at its bifurcation. The heart is then placed in a secure Teflon container filled with cold saline or other preservation solution and then placed in a cooler filled with ice.

Ideally, the donor cardiac graft should be reperfused in the recipient within 4 to 6 h of its excision from the donor.[20] Ischemic times greater than 4 h have resulted in decreased recipient survival. If the recipient requires reconstruction of both pulmonary arteries, then the branch pulmonary arteries are divided at the level of the pulmonary hilum. Additional length of the ascending aorta may be required for recipients

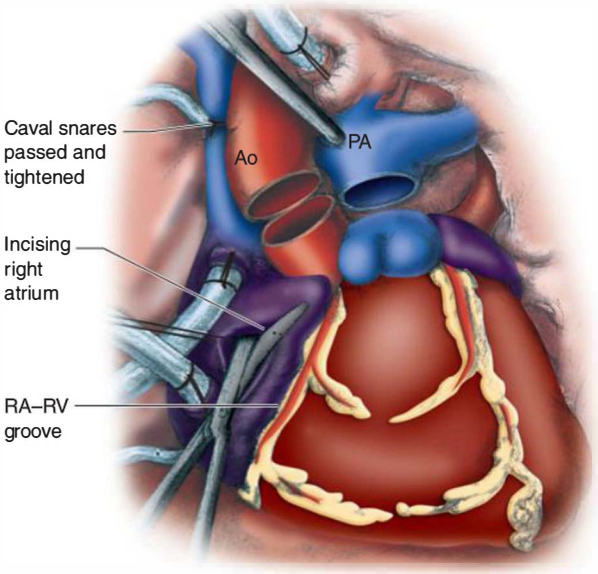

**FIGURE 50-1** Excision of the recipient heart. (Reproduced with permission from Shumway SJ. *Thoracic Transplantation*. In: Shumway SJ, Shumway NE (eds). Boston: Blackwell Science, Inc., June 1995. Fig. 15-3.)

with hypoplastic left heart syndrome or with L-transposition of the great vessels.[21]

## Recipient Cardiectomy

If the recipient has undergone previous cardiac surgery, it is helpful to obtain a CT scan of the chest to demonstrate the proximity of the heart or other critical structures (e.g., LVAD outflow graft) to the undersurface of the sternum. All recipients are fully heparinized. Bicaval cannulation with caval snares and a standard aortic cannula are used. The SVC is cannulated high enough to facilitate the SVC anastomosis. The recipient is then placed on total cardiopulmonary bypass and an aortic cross-clamp is placed across the ascending aorta. When bicaval anastomoses are being performed, the recipient cuffs are fashioned at the level of the superior and inferior vena cava after the interatrial groove is developed in order to facilitate excision of the right atrium. Generally, the native right atrium is open anteriorly and the right atriotomy is extended superiorly, trimming off the right atrial appendage (see Fig. 50-1). The right atriotomy is then extended inferiorly into the coronary sinus. Each great vessel is divided above its semilunar valves. The cardiectomy continues by opening the roof of the left atrium. The left pulmonary veins are identified and the left atriotomy continues along the atrioventricular groove. The pericardial sac is irrigated with cold saline solution to remove debris. The left atrial cuff is further trimmed as needed. In patients with ischemic cardiomyopathy, the epicardial portion of the left atrial cuff may require cauterization.

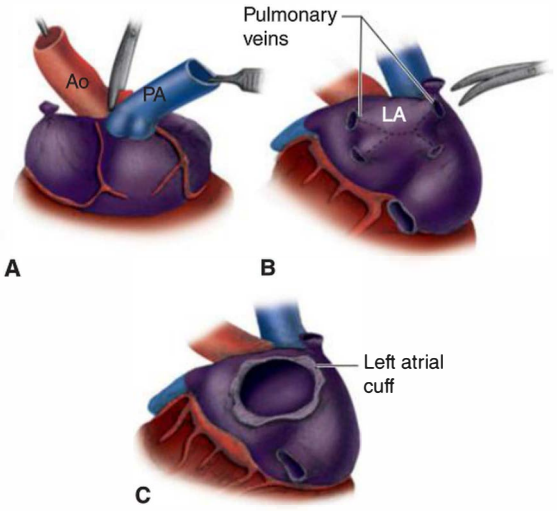

**FIGURE 50-2** Preparation of the donor heart. (Reproduced with permission from Shumway SJ. *Thoracic Transplantation.* In: Shumway SJ, Shumway NE (eds). Boston: Blackwell Science, Inc., June 1995. Fig. 15-2.)

## Donor Graft Implantation

After removing the donor heart from its sterile container, the aorta and pulmonary arteries are separated (see Fig. 50-2). The donor pulmonary artery is trimmed just proximal to its bifurcation. The donor aorta is likewise trimmed just proximal to the takeoff of the innominate artery. The pulmonary veins are identified and connected in a cross-like manner. The left atrial cuff is then trimmed appropriately. The mitral valve is inspected. Next, the inferior vena cava is located. Any patent foramen ovale is identified and closed. If biatrial anastomoses are planned, the inferior vena cava is opened curvilinearly toward the right atrial appendage to avoid the sinus node. The SVC is closed circumferentially with two layers of running 4-0 polypropylene suture. The donor heart is then kept in cold saline solution until implantation. Retrograde cold blood cardioplegia may be delivered via the coronary sinus when the ischemic time exceeds 4 h.

Implantation commences with the left atrial anastomosis. The donor heart is typically wrapped in a cold saline sponge. The donor and recipient left atrial cuffs are anastomosed in an end-to-end fashion with a running 3-0 polypropylene suture (see Fig. 50-3). Just before this suture line is completed, the left atrium is filled with cold saline solution, and the suture line is secured. Some surgeons prefer to leave a vent in the left atrium in order to keep the heart decompressed. When bicaval anastomoses are planned, the IVC anastomosis is performed in an end-to-end fashion with a running 4-0 polypropylene suture followed by an end-to-end SVC anastomosis. If biatrial anastomoses are planned, the right atrial cuff anastomosis is performed at this time. Finally, the main pulmonary arterial and aortic anastomoses are performed in an end-to-end fashion with running

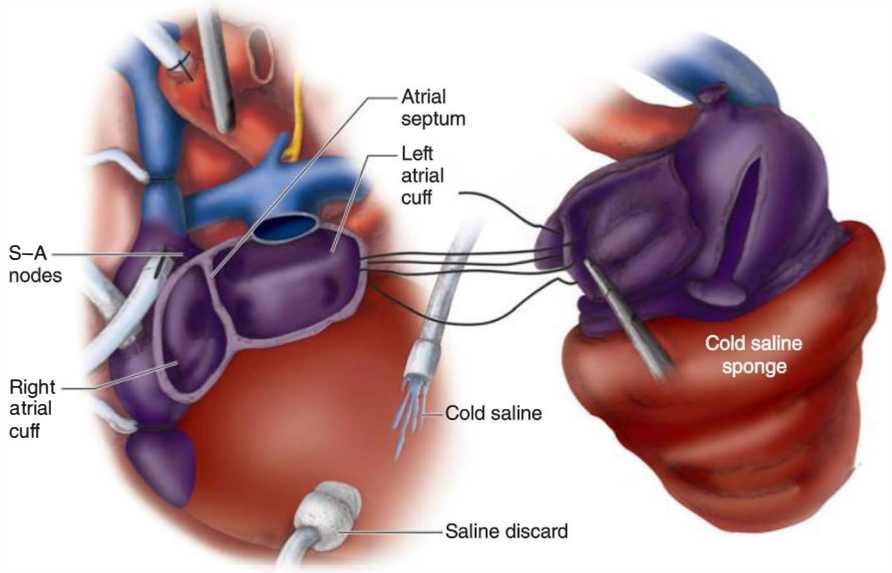

**FIGURE 50-3** Performing the left atrial anastomosis. (Reproduced with permission from Shumway SJ. *Thoracic Transplantation*. In: Shumway SJ, Shumway NE (eds). Boston: Blackwell Science, Inc., June 1995. Fig. 15-4.)

4-0 polypropylene sutures (see Fig. 50-4).[22] Care must be taken to fashion the pulmonary arteries to the appropriate length to avoid kinking. Kinking of a reconstructed pulmonary artery can cause right heart failure postoperatively. Active warming of the recipient begins as the great vessel anastomoses are being performed.

Prior to release of the aortic cross-clamp, it is advisable to place a root vent in the ascending aorta to ensure adequate de-airing. The recipient receives a dose of intravenous steroids prior to release of the aortic cross-clamp. In addition, it is helpful to start isoproterenol at 0.01 to 0.02 μg/kg/min as a chronotrope. Intravenous epinephrine and milrinone are also excellent perioperative drugs for the newly reperfused donor organ. Once the aortic cross-clamp is released, a period of allograft reperfusion is important to resuscitate the graft. Once the heart is beating vigorously and the patient is warm, the vent in the left atrium is removed. The aortic root vent is left in place until, by transesophageal echocardiography, it is clear that adequate de-airing has been performed. The recipient is then carefully separated from cardiopulmonary bypass. Transesophageal echocardiography is helpful in evaluating graft performance. Two temporary atrial pacing wires are placed on the donor right atrium, and two temporary ventricular pacing wires are placed on the donor right ventricle.

## POSTOPERATIVE MANAGEMENT

### ICU Care

The principles of posttransplant care are similar to those used in the routine postoperative care of cardiac surgical patients. Hemodynamic monitoring is used, including measurements of systemic arterial pulmonary arterial and central venous pressures measurements, cardiac output and index, urine output, and mixed venous saturation ($Svo_2$). Optimizing gas exchange is important and particular attention is paid to keeping arterial $Pco_2$ levels relatively low and avoiding a base deficit, particularly in the setting of pulmonary hypertension. Chest tube output, coagulation parameters, and serial hemoglobin levels are closely monitored. Significant blood loss is replaced with packed red blood cell transfusions. Any coagulopathy is corrected. Serum hemoglobin levels are kept above 9 g/dL to promote adequate tissue oxygen delivery capacity. Urine output is closely monitored and diuretics are used for volume overload. The urine output is nominally maintained at greater than 30 mL/h.

The following hemodynamic parameters are considered physiologic and optimal: systemic blood pressure greater than 90 mm Hg, mean arterial pressure greater than 60 mm Hg, central venous pressure between 5 and 18 mm Hg, pulmonary artery pressure less than or equal to one-third of the systemic blood pressure, cardiac indices greater than 2 L/min/$m^2$, and $Svo_2$ levels greater than 65. Ventilator weaning is begun as soon as the patient is awake and determined to be hemodynamically stable without evidence of mediastinal bleeding.

Several unique physiologic features of a cardiac allograft should be considered in the early postoperative period.[23] One distinct characteristic of the transplanted heart is that it is totally denervated, which may result in a reduction in its intrinsic heart rate. Consequently, a chronotropic catecholamine agent is routinely used in the early postoperative

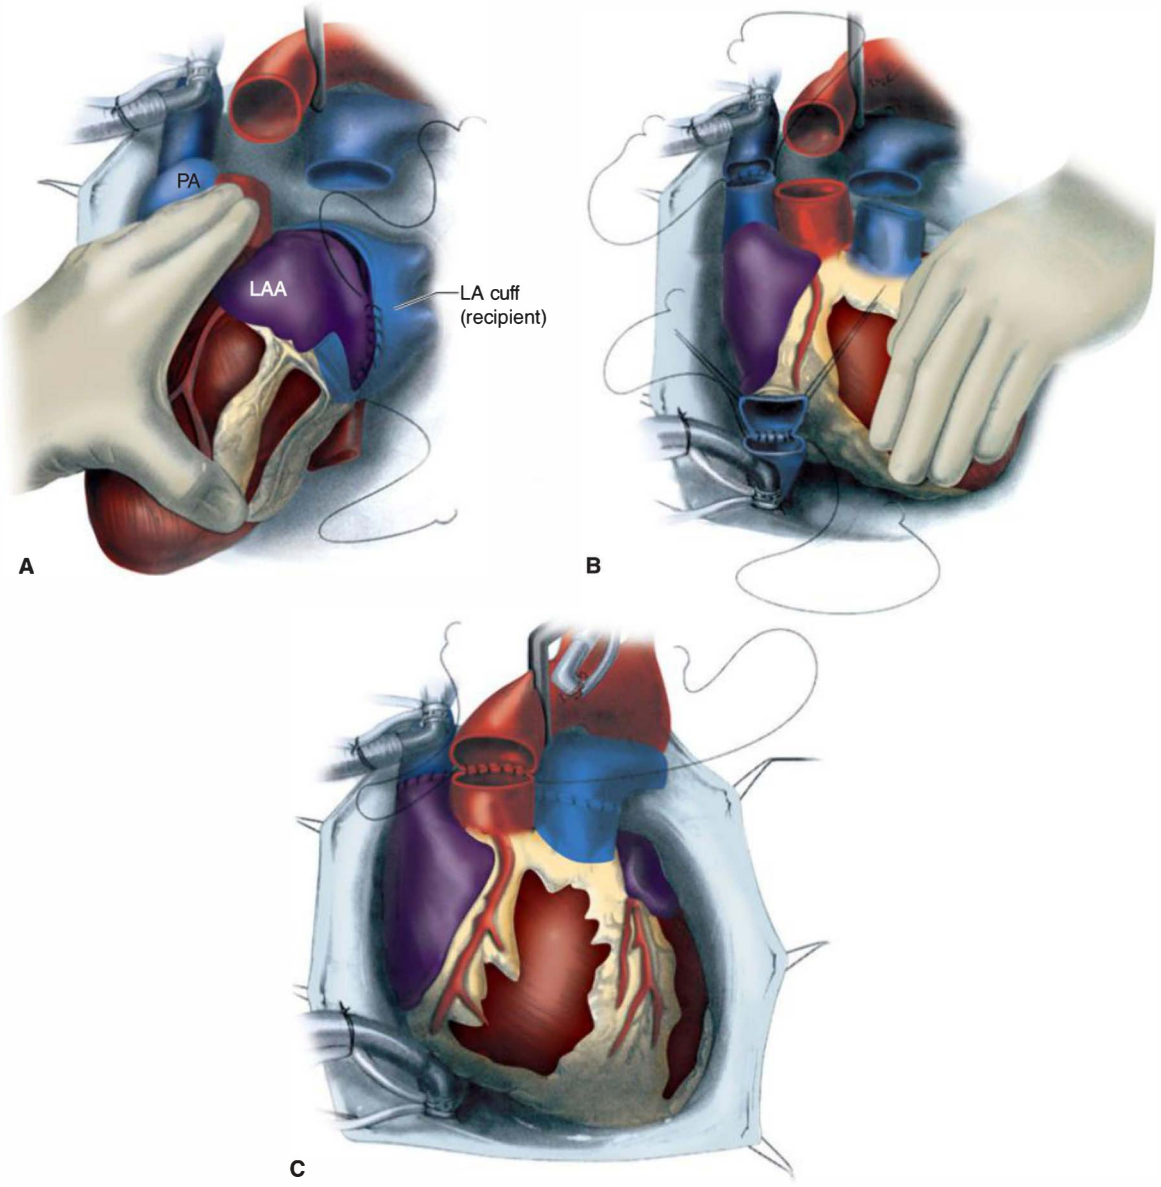

**FIGURE 50-4** Performing the caval and great vessel anastomoses. (Reproduced with permission from John R, Liao K. Orthotopic heart transplantation. *Oper Tech Thorac Cardiovasc Surg* Summer 2012;15:(2):138–146. Copyright Elsevier. Fig. 4.)

period. Typically, isoproterenol is infused at a dose of 0.01 to 0.03 μg/kg/min. The goal heart rate is set to over 90 beats/min. If the heart rate fails to respond to the isoproterenol drip, epicardial pacing (preferably atrial pacing), is initiated at 90 beats/min. The bradycardia typically resolves spontaneously within 48 h postoperatively with weaning of the isoproterenol drip. Besides its chronotropic effect, isoproterenol often improves cardiac output by reducing pulmonary vascular resistance. Cardiac output and $Svo_2$ should be closely monitored during the weaning of isoproterenol because both parameters can drop despite maintenance of an adequate intrinsic heart rate. Terbutaline may be required to keep the heart rate over 60 beats/min once the patient resumes oral intake. Occasionally, a permanent pacemaker may be necessary if the heart rate remains less than 60 over a sustained period of time.[24]

A second β-adrenergic agent such as epinephrine is added in the early postoperative period if the patient's cardiac output is inadequate or if isoproterenol leads to excessive tachycardia or significant arrhythmias. If the patient's systemic blood pressure and peripheral vascular resistance are low, a vasoactive agent such as vasopressin is added. Vasopressin is

preferred over other vasoconstrictors due to its limited effect on pulmonary vascular resistance. A milrinone infusion is initiated in the setting of significant pulmonary hypertension or right heart failure.

Low cardiac output early after transplantation can be multifactorial. The increased use of older marginal donor hearts, prolonged donor heart ischemic time, and mismatch of donor and recipient weight all contribute to early graft dysfunction. The treatment algorithm for low cardiac output is similar to that used in routine cardiac surgery patients. Maintaining an adequate heart rate with an isoproterenol infusion or atrial pacing is crucial to optimizing early cardiac allograft function, followed by maintaining adequate preload by maintaining central venous pressures between 10 and 18 mm Hg. One or more β-adrenergic inotropic agents are usually required in the early postoperative period. Milrinone is useful in the setting of significant pulmonary hypertension and/or right ventricular dysfunction. If low cardiac output persists despite these interventions, an echocardiogram should be obtained to rule out cardiac tamponade and assess left and right ventricular function.

Early graft failure is unusual but often results from poor myocardial protection or early acute allograft rejection. Early endomyocardial biopsy to detect cellular rejection or immunofluorescence staining to identify humoral rejection may be required. True hyperacute cardiac rejection is extremely rare in the modern era of transplantation. Progressive left ventricular dysfunction due to primary graft failure may require further support with an intra-aortic balloon pump. A left or biventricular assist device may be required if multiorgan failure and severe acidosis cannot be reversed by medical management. Short-term extracorporeal ventricular assist devices can be used to support the failed heart for up to 2 weeks to allow the myocardium to recover from ischemia or to allow antirejection treatment to work. Ventricular assist devices are inserted in a standard fashion, with the inflow cannula inserted in the appropriate atrium and outflow cannula inserted into the appropriate great vessel.[25]

Recipients with a preoperative pulmonary vascular resistance above 3 Wood units are at an increased risk of developing elevated pulmonary vascular resistance in the early postoperative period, resulting in acute right heart failure. Several measures can be taken to prevent right heart failure, including using a slightly "oversized" donor and/or using a graft from a male donor to a female recipient. Donor graft ischemic time must be minimized. Excessive blood and blood product transfusions can be avoided by giving activated factor VII to correct significant coagulopathy. Hypoxia and hypercapnia should be corrected. Early initiation of milrinone and inhaled nitric oxide can be used for their pulmonary vasodilatory effects. Finally, leaving the chest open can be helpful in avoiding mechanical compression of an edematous, struggling right ventricle.[26] Inserting a right ventricular assist device in the setting of a high PVR is of limited utility with generally poor clinical outcomes.

## Immunosuppressive Management

Systemic immunosuppressive therapies are used to prevent or treat cardiac allograft rejection while minimizing both drug toxicities and the major sequelae of immunosuppression, namely infection and malignancy. Most immunosuppressive regimens consist of "triple-therapy" immunosuppression: corticosteroids, calcineurin inhibitors, and antiproliferative agents.[27,28]

Corticosteroids are nonspecific anti-inflammatory agents, generally effecting significant lymphocytic depletion. They reversibly block T cell and antigen-presenting cell-derived cytokine and cytokine-receptor expression that otherwise would occur as a consequence of T-cell activation. The nonspecific action of steroids leads to many side effects such as: weight gain, glucose intolerance, gastric distress, hyperlipidemia, and hypertension.

Calcineurin inhibitors, namely cyclosporine, a small fungal cyclic peptide, and tacrolimus-FK506 (Prograf), a macrolid antibiotic, have become the cornerstone of immunosuppressive therapy in solid organ transplantation. Cyclosporine binds to a group of immunophilins called cyclophilins, which are important biologic molecules present in all tissues. Tacrolimus forms a complex with FK506 binding proteins (FKBP). These complexes bind to calcineurin, a pivotal enzyme in T-cell IL-2 production, thereby inhibiting cytokine transcription by CD4 cells. Blockade of cytokine production and cytokine-receptor expression inhibits T-cell proliferation and differentiation so that the various effector arms of the immune response are not activated. Compared to cyclosporine, Prograf causes less nephrotoxicity.[29]

The antiproliferative agent, mycophenolate mofetil (MMF, CellCept), is a selective inhibitor of the de novo pathway of purine biosynthesis, thereby providing more specific and potent inhibition of T- and B-cell proliferation. MMF causes less bone-marrow suppression compared with the other agents in its class.

Daclizumab (Zenapax) is a monoclonal antibody that is an IL-2 receptor antagonist, which is typically useful in the setting of renal insufficiency or in recipients suffering from gastrointestinal dysfunction for an extended period of time.

## Immunosuppressant Dosing

Methylprednisolone is typically administered to the cardiac transplant recipient preoperatively (1000 mg IV) and upon reperfusion of the donor heart (500 mg IV). Additional methylprednisolone (125 mg IV) is dosed every 8 h for three doses after the patient has returned to the intensive care unit. Prednisone is initiated at 1 mg/kg/day in two divided doses and progressively tapered over a 4-week period by 5 mg/day to 20 mg twice a day (Table 50-6). Patients must be free of rejection for 3 months before steroids are completely withdrawn.

Prograf is typically started within the first three postoperative days if the patient's renal function is normal. The

**TABLE 50-6: Typical Prednisone Taper Regimen**

| | |
|---|---|
| Month 1 | Prednisone 0.3 mg/kg/d |
| Month 2 | Prednisone 0.2 mg/kg/d |
| Month 3 | Prednisone 0.1 mg/kg/d |
| Month 4 | Prednisone 0.05 mg/kg/d or 2.5 mg/d |
| Month 5 | Prednisone discontinued |

starting dose of Prograf is 0.5 mg twice a day and is increased to 2 mg twice a day depending on the serum drug levels. The patient's renal function or creatinine is closely monitored during Prograf dosing. The 12-h trough level of Prograf is maintained between 10 and 15 mg/L immediately after transplant, and tapered afterward (Table 50-7).

Mycophenolate mofetil (1500 mg PO) is given preoperatively and continued postoperatively (2–3 g IV/PO per day in two divided doses). Serum levels of MMF are maintained at 2 to 4 mcg/ml and the dose is further titrated to keep the white blood cell count above 4000/dL.

## Treatment of Cardiac Allograft Rejection

Rejection of the transplanted heart is a major cause of morbidity and mortality in the first year after heart transplantation. Rejection is classified as hyperacute, acute cellular, acute humoral (antibody-mediated), or chronic (allograft vasculopathy).[30]

*Hyperacute rejection* occurs within minutes to hours of allograft reperfusion and is caused by preformed antibodies to ABO blood group antigens, HLA, or endothelial antigens. With ABO matching of recipients to donors and prospective and/or virtual crossmatching of patients who have been previously sensitized to HLA, hyperacute rejection is rare. When it does occur, it is catastrophic because preformed antibodies bind to endothelial antigens on the transplanted heart, resulting in complement-mediated coronary thrombosis and marked cardiac allograft dysfunction.

*Acute cellular rejection* may occur at any time after transplantation but occurs most commonly in the first 3 to 6 months. It is a T cell–mediated response with myocardial infiltration by lymphocytes and macrophages with resultant myocytolysis. The diagnosis is made by endomyocardial biopsy with a standardized grading scheme ranging from mild to moderate to severe acute rejection.[31] Moderate rejection by endomyocardial biopsy is associated with mononuclear cell infiltrates and myocytolysis and generally prompts antirejection therapy that varies according to the histological severity (i.e., grade of rejection) and graft performance. Patients with acute cellular rejection may display no signs or symptoms, but often notice mild fatigue or dyspnea. Signs of right ventricular dysfunction are often consistent with elevated jugular venous pressures. More severe rejection may be associated with signs of left ventricular dysfunction. Therapy may include intravenous or oral steroids, monoclonal or polyclonal antilymphocyte agents, or an increase or change in existing immunosuppressant dosing.

Routine endomyocardial biopsy remains the gold standard for monitoring and grading of cardiac allograft rejection. The first consensus statement on grading rejection based on endomyocardial biopsy specimens was published in 1990. It described the various histologic patterns of inflammation in biopsy specimens and is summarized in Table 50-8.

*Antibody-mediated rejection (AMR)* refers to allograft injury resulting from activation of the complement system, typically by recipient-generated antibodies directed against the allograft tissue antigens. Although AMR most commonly occurs months to years following transplantation, a rare subtype, hyperacute rejection, can occur within minutes to hours after transplantation. Risk factors for developing AMR include history of multiple pregnancies, previous transplantation, blood transfusions, sensitization by OKT3 induction therapy, and use of ventricular assist devices.[32,33]

Diagnosing AMR can be difficult. The criteria for the diagnosis of AMR include complement deposition in capillaries (especially CD4), capillary endothelial swelling, and inflammation involving the capillaries, most typically macrophage infiltrates located in the vessel wall and lumen. A consensus statement on diagnosing AMR was established by the ISHLT in 2004; AMR 0 is reported for those cases that provide no evidence of AMR, whereas AMR 1 is used to denote a diagnosis of AMR.[34]

Endomyocardial biopsy is generally performed weekly for the first postoperative month, after which biopsies are

**TABLE 50-7: Typical Prograf Blood Level Taper Schedule**

| | |
|---|---|
| 0–3 months | 10–15 mg/L |
| 3–6 months | 8–12 mg/L |
| 6–9 months | 6–12 mg/L |
| 9–12 months | 6–12 mg/L |
| After year 1 | 6–10 mg/L |
| Off prednisone | 6–10 mg/L |

**TABLE 50-8: International Society for Heart Lung Transplantation (ISHLT) 1990 Classification of Acute Cellular Rejection in Transplant Endomyocardial Biopsy Specimens**

Grade 1A: Focal, mild acute rejection
Grade 1B: Diffuse, mild acute rejection
Grade 2: Focal, moderate acute rejection
Grade 3A: Multifocal, moderate rejection
Grade 3B: Diffuse, borderline severe acute rejection
Grade 4: Severe acute rejection

obtained at less frequent intervals. The clinical manifestations of cardiac transplant rejection are variable and may or may not correlate with the histologic severity of rejection. During an episode of rejection, the clinical presentation can range from no symptoms to profound heart failure. Arrhythmias and sudden death resulting from rejection have also been reported following heart transplantation. Ischemia may be produced secondary to cardiac allograft vasculopathy (Typical angina is usually absent owing to the fact that the donor heart is denervated.

Patients presenting with at least grade 3A rejection are treated with pulse steroids in the form of prednisone 1000 mg/day for three consecutive days. If such rejection is encountered within the first postoperative month or during the initial hospitalization, three doses of intravenous methylprednisolone (10 mg/kg/day) are administered. Dosing of other maintenance immunosuppression agents are adjusted to obtain optimal levels. Patients with any positive grade of biopsy and hemodynamic compromise are admitted to the hospital and receive intravenous thymoglobulin, a polyclonal antibody. If biopsy specimens of hemodynamically compromised patients show no evidence of cellular rejection, immunofluorescence studies should be performed and may confirm humoral-mediated rejection. Plasmapheresis is initiated if humoral rejection is strongly suspected or confirmed. Occasionally, empiric antirejection therapy may be started for hemodynamically compromised patients without a definitive biopsy result or diagnosis. If the patient has had a positive donor-specific crossmatch or has clinic signs of early acute rejection, early immunosuppression is directed toward decreasing the humoral antibody load and B-lymphocyte proliferation. Plasmapheresis may also be performed to rapidly decrease antibody load.[35]

## Complications of Immunosuppressive Therapy

Each immunosuppressive agent carries a host of side effects. Steroids are known to cause Cushingoid features, osteoporosis, peptic ulcer disease, and glucose intolerance. Reduction and elimination of steroids is the most effective means to ameliorate these side effects. Occasionally, oral hypoglycemic medications and even insulin are used to treat hyperglycemia resulting from steroid use. Important side effects of cyclosporine include renal dysfunction and hypertension. Careful monitoring of serum cyclosporine levels with an eye towards achieving the lowest effective levels helps mitigate these side effects.

### INFECTION

Despite improved immunosuppressive therapies, infection remains a serious complication in cardiac transplant recipients. In the immediate postoperative period, the most common infection is ventilator-associated pneumonia resulting from prolonged intubation. Early extubation and aggressive pulmonary toilet measures are critical to preventing hospital acquired pneumonia. Pneumonia is treated with broad-spectrum antibiotics with antibiotic sensitivities closely followed.

Despite the prophylactic use of trimethoprim–sulfamethoxazole, CMV infections are still a major source of morbidity after transplantation. Patients with CMV-negative serologies who receive hearts from CMV-positive donors are at an increased risk for developing serious CMV infections. Valganciclovir has replaced ganciclovir and is currently recommended for CMV prophylaxis if the donor and/or recipient have positive CMV serologies. If both the recipient and donor have negative CMV serologies, valganciclovir prophylaxis is generally not indicated. The dosing of valganciclovir is based on the patient's renal function, with 900 mg/day being a typical dose in patients with normal renal function and 450 mg/day for patients with mild-to-moderate renal impairment.

### MALIGNANCY

The risk of malignancy in solid organ transplant recipients is elevated compared with the general population. This is believed to be a result of long-term immunosuppression compromising the ability of the patient's immune system to reverse precancerous tissue changes and incipient malignancy. According to the registry of the International Society for Heart and Lung Transplantation (ISHLT) in 2008, the cumulative prevalence of malignancy in heart transplantation recipients is 2.9, 15.1, and 31.9 percent at 1, 5, and 10 years, respectively.[36]

Skin cancer is the most common malignancy in heart transplant recipients, with an incidence of 1 percent at 1-year posttransplant, 10 percent at 5 years, 20 percent at 10 years, and 29 percent at 14 years. When treated early, most forms of skin cancer do not result in death. Lymphoproliferative malignancies are much less frequent than skin cancer. The incidence of lymphoproliferative malignancies is 1, 2, 4, and 5 percent at 1, 5, 10, and 14 years, respectively, after transplantation, and are much more difficult to cure. The most common solid organ malignancies in heart transplant patients are prostate, lung, and breast cancers. The incidences of these malignancies are similar to those in the general population. The principles of treating malignancies in heart transplant patients are the same as for the general population. Attenuation of immunosuppressive regimens in afflicted patients is useful for controlling tumor progression.

### CARDIAC ALLOGRAFT VASCULOPATHY

CAV, also known as accelerated graft arteriosclerosis, generally refers to concentric luminal narrowing of the epicardial and intramural coronary arteries. This process generally occurs months to years following transplantation and is currently the limiting factor in long-term cardiac allograft survival. More than one-half of adult heart transplant recipients exhibit angiographically detectable

CAV by 10 years posttransplantation. In the 2009 ISHLT Registry report on data from more than 84,000 heart transplant recipients, the overall prevalence of CAV in survivors at 1, 5, and 10 years after transplantation was 8, 30, and 51 percent, respectively. Early CAV, diagnosed within the first year after transplantation, is a powerful predictor of 5-year mortality. Compared to conventional coronary angiography, intravascular ultrasound (IVUS) can detect coronary intimal thickening at a much earlier stage. Some studies show that first-year IVUS data can provide an early marker for long-term outcomes. The most important predictors for the development of CAV were found to be older donors, donor history of hypertension, younger recipients, number of HLA–DR mismatches, and recipient pretransplant diagnosis of ischemic heart disease. A variety of immune and nonimmunologic factors contribute to the pathogenesis of CAV. It is believed that CAV arises with ischemic injury to the donated organ's endothelial cells. In response, both immunologic and nonimmunologic factors act on the endothelium, initiating a cascade of immunologic responses. Eventually, upregulation of complement, inflammatory mediators, and cytokines leads to the progression of CAV. Immunosuppressive medications, such as cyclosporine and corticosteroids, are now thought to contribute to endothelial cell injury and ultimately to the intimal hyperplasia characteristic of CAV.[37]

Current medical therapies are not effective and can only slow the progression of CAV. Proliferation inhibitors (e.g., sirolimus and everolimus), and statin drugs have demonstrated some benefit in preventing CAV. Primary strategies for managing CAV include modification of cardiovascular risk factors, including control of hypertension and diabetes, smoking cessation, weight loss, surgical and percutaneous revascularization, and retransplantation. For patients with severe CAV, revascularization with drug-eluting stents or coronary bypass grafting is considered palliative therapy, with retransplantation offering a more definitive solution.

## CLINICAL OUTCOMES

The median survival after cardiac transplantation is currently 10 years for the entire cohort of adult and pediatric recipients, with a median survival of 13 years for those surviving to 1 year. Median survival rates have steadily improved from 8.3 years during the 1980s to 10.4 years during the 1990s—and survival has further improved since 2000. The mortality risk is highest in the first 6 months after transplant; the improvement in survival most recently has been attributed to lower mortality during this early posttransplant period. Past 1 year after transplant, the mortality rate is fairly constant, approximately 3 to 4 percent/year, which is higher than the mortality rate of the general population. In the last 20 years, long-term survival of those patients who are alive at 1 year has not significantly improved, and it is likely that the potential for further survival improvement now lies in approaches that reduce long-term mortality rates.

Graft failure is the leading cause of death in the first 30 days after transplant (39 percent of deaths) and continues to remain prominent throughout the early posttransplant period. Within the first 30 postoperative days, most cases are due to primary graft failure. Subsequent to this period, graft failure is more likely due to chronic graft injury from AMR or CAV. Acute rejection is now a fairly uncommon cause of mortality, responsible for no more than 11 percent of deaths.

Deaths related to CAV become prominent between 1 and 3 years after transplantation and are responsible for 10 to 15 percent of deaths thereafter. The rate of death from malignancy also increases in this period and is responsible for approximately 20 percent of deaths 3 or more years after transplant. The risk of death due to infection is highest in the first year after transplant, comprising 29 percent of deaths between 2 and 12 months posttransplant, after which the risk decreases to about 10 percent. Renal failure as the primary cause of death increases steadily after transplant.

Within the first year after cardiac transplantation, patients bridged to heart transplantation with mechanical circulatory support devices appear to have a higher risk of death compared with recipients not requiring mechanical circulatory support. Patients with congenital heart disease carry a higher mortality risk, and patients with ischemic cardiomyopathy fare somewhat worse than those with nonischemic cardiomyopathy. Comorbidities that are significant risk factors for recipient mortality include the need for hemodialysis, mechanical ventilation, blood transfusion, and recent infection. Recipient and donor age, allograft ischemic time, and serum markers of hepatic and renal dysfunction also affect recipient survival.

Mortality rates at 5 years posttransplant are affected to a large degree by factors similar to those affecting 1-year mortality. Additional risk factors at this point include past pregnancy, female allograft allocation to a male recipient, and prior stroke. The risk factors that affect 10-year mortality rates are similar to those that affect 1- and 5-year mortality rates. The additional significant predictor of risk at 10 years after transplant is gender—female recipients and male recipients receiving female allografts appear to have a higher risk of death than males receiving male allografts. A PRA level of more than 10 percent is also a significant mortality risk factor, although the increased risk is modest.

Only a few factors are associated with 20-year mortality rates. Younger recipient age at transplant favor 20-year survival. Donor age and allograft ischemic time, consistent predictors of mortality at 1, 5, 10, and 15 years after transplant, are not associated with mortality at 20 years. A possible explanation for this is that during the 1980s, heart allografts from older donors were not routinely used and longer allograft ischemic times were avoided. Recipients who underwent transplant for nonischemic cardiomyopathy fared better than those with ischemic cardiomyopathy, and patients with congenital heart disease fared better than those who underwent transplant for nonischemic cardiomyopathy.

## FUTURE DIRECTIONS

The last four decades have witnessed steady improvement in outcomes among cardiac transplant recipients. This improvement has been attributed to better management of heart failure patients on the waiting list, introduction of new immunosuppressants, the increasing use of LVADs as bridge support, and improved donor organ preservation. However, many obstacles remain. Limited donor organ availability has remained constant for decades. The potential solutions for donor organ shortage reside in expanding the pools of alternative donors for alternative recipients who are excluded by conventional criteria and increasing efforts in xenotransplantation research, which could potentially solve the donor shortage. A portable organ perfusion device to continuously perfuse the donor heart to extend the current preservation time limit of 6 h will improve organ availability and provide opportunities for better matching. Advances in small, durable, and implantable ventricular assist devices as destination therapy will ease the increasing demand for donor hearts and ultimately delay or obviate heart transplantation in many end-stage heart failure patients.

Mortality from infection, malignancy, and renal failure can be attributed to overly aggressive immunosuppressive therapies. Deaths from rejection, CAV, and late graft failure often result from inadequate immunosuppression. Consequently, there is a need to assess the individual transplant recipient's immune status and risks more accurately and tailor immunosuppressive therapies accordingly. Immune surveillance with noninvasive techniques may lead to earlier detection of rejection and more efficient treatment. Finally, the continued development of new and improved immunosuppressants will undoubtedly reduce the side effects currently associated with immunosuppressive regimens.

## CARDIAC TRANSPLANTATION BOARD REVIEW QUESTIONS (CHAPTER 50)

1. Which of the following is a contraindication to cardiac transplantation?
   A. Recipient PVR is greater than 5 Wood units.
   B. Recipient had breast cancer 5 years ago.
   C. Recipient was transfused 2 months ago.
   D. Recipient had an LVAD placed 2 months ago.
   E. Recipient has a creatinine of 2.0.

2. Which of the following situations carries the highest potential operative mortality?
   A. A younger recipient receives a younger donor heart with a short ischemic time.
   B. A younger recipient receives an older donor heart with a long ischemic time.
   C. An older recipient receives a younger donor heart with a long ischemic time.
   D. An older recipient receives a younger donor heart with a short ischemic time.
   E. An older recipient receives an older donor heart with a long ischemic time.

3. What is the appropriate strategy prior to transplantation in a potential recipient who has received a recent blood transfusion?
   A. Perform a prospective crossmatch.
   B. Perform a virtual crossmatch.
   C. Wait 2 weeks, perform PRA, and then list for a crossmatch.
   D. Accept an appropriate donor and wait for the retrospective crossmatch.
   E. Pretreat with thymoglobulin and adjust postoperative immunosuppression according to the retrospective crossmatch.

4. What part of the donor heart is at greatest risk for compromise during procurement?
   A. Donor left atrium on the right side
   B. Donor left atrium on the left side
   C. Donor right atrium near the SVC
   D. Donor right atrium near the IVC
   E. Donor pulmonary artery

5. At 5 years after cardiac transplantation, what percentage of recipients will have CAV?
   A. 10 percent
   B. 20 percent
   C. 30 percent
   D. 40 percent
   E. 50 percent

## ANSWERS

1. **Answer: A.** The recipient PVR should ideally be less than 5 Wood units. Patients that are cancer-free after 5 years are considered acceptable for transplantation. Transfusion within 2 months mandates a PRA prior to transplantation. A patient with placement of an LVAD 2 months ago would be approaching adequate time for transplant listing. Elevated creatinine is not a contraindication to transplantation but warrants adjustment of antirejection therapies.
2. **Answer: E.** The combination of an older recipient with possible comorbidities and an older donor heart that is less resilient to an extended period of ischemia is associated with the highest potential operative mortality. In general, young donor organs will do well, even with extended ischemic times. An older donor heart should not be used in a younger recipient unless there is no alternative.
3. **Answer: A.** Although a prospective crossmatch will limit the number of potential donors, this is the safest approach. A virtual crossmatch still needs a current PRA and a 2-week waiting period from the last transfusion. After waiting 2 weeks, a crossmatch may not be necessary. Accepting an appropriate donor based only on a retrospective crossmatch carries an undue risk of AMR. Pretreatment with thymogloblin will not eliminate all risk of AMR.
4. **Answer: B.** The confluence of the left pulmonary veins can be quite short and difficult to appreciate during the procurement, particularly when leaving a cuff of left atrium for concomitant left lung procurement.
5. **Answer: C.** Approximately 30 percent of recipients will have evidence of CAV 5 years after transplantation.

# 51 Mechanical Circulatory Support

*Clinton D. Kemp*
*John V. Conte*

## INTRODUCTION

The history of mechanical circulatory support (MCS) parallels that of cardiac surgery and began with the introduction of the Gibbon bubble oxygenator.[1] That revolutionary device opened up the field of cardiac surgery and was one of the major medical advances of the last century. Soon after the use of cardiopulmonary bypass (CPB) became commonplace, failure to wean from CPB became recognized as a problem whose solution required temporary cardiac support to enable postcardiotomy cardiac recovery. Spencer and coworkers utilized postoperative femoral CPB in 3 patients, one of whom survived and ushered in the modern era of temporary MCS.[2] This was soon followed by the use of the first extracorporeal mechanical assist device by DeBakey et al. in 1964 and the subsequent development of the intraaortic balloon counterpulsation device, variations of which are still in use today. Kantrovitz, Cooley, Oyer, Devries, and others were responsible for other notable firsts including the first successful bridge to transplant (BTT) and first successful total artificial heart (TAH) implant.[3-7] Notable clinical landmarks in the history of MCS are shown in Table 51-1. In this chapter, we review the major indications for MCS as well as the various options available.

## INDICATIONS FOR MECHANICAL CIRCULATORY SUPPORT

Generally speaking, there are three primary indications for the use of MCS: "bridge to recovery" (BTR), "bridge to transplant" (BTT), and "destination therapy" (DT). Data on MCS devices implanted in the United States are kept by the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS).[8] According to the second INTERMACS annual report that provides information on FDA-approved device implantations from 2006 to 2009, the most common indication for MCS was BTT (45.4 percent), followed by DT (9.2 percent), and BTR (2.3 percent) (Fig. 51-1). Bridge to candidacy for transplantation, or "bridge to decision" is a fourth category that has emerged and includes patients whose candidacy for transplantation has not been decided for medical or social reasons. This accounted for 41.9 percent of all device implantations during this time period. Within each of these categories, specific device therapy can be broken down into short-term (days to weeks) and long-term (weeks or longer) therapy.

BTR is used in patients who have severe, acutely decompensated heart failure from potentially reversible causes who may eventually recover myocardial function but whose native heart is unable to provide sufficient end organ perfusion without assistance. This therapy serves to unload the damaged heart to allow remodeling and recovery while providing improved tissue perfusion to vital organs. Indications for BTR therapy include postcardiotomy support following cardiac surgery, acute viral cardiomyopathic syndromes, hemodynamic instability, and myocardial infarction. For BTR, short-term devices are typically used as their cost is lower and implantation is easier. In certain patients in extremis and in whom neurologic status and candidacy for cardiac transplantation or longer term mechanical assist therapy is unknown, a short-term device can potentially serve as a bridge to a long-term device in a "bridge to a bridge" scenario in which the short-term device is replaced by a long-term device for DT or BTT prior to cardiac transplantation. BTR has also been used in patients with chronic advanced CHF with the hope that a period of unloading will enable ventricular remodeling and recovery, allowing device removal.

BTT is currently the most common indication for MCS today. The intent of device therapy for this group of patients is not only to provide temporary support for a failing heart but also to improve end organ function, making the potential recipient healthier prior to transplantation. Studies have demonstrated improved survival to transplantation and improved posttransplant survival compared with inotrope supported patients.[9]

DT is the phrase coined to describe the use of left ventricular assist devices (LVADs) as a final therapy to support patients until their death. These patients are those

**TABLE 51-1: Clinical Milestones in the Development of Mechanical Circulatory Assistance**

| Year | Investigator | Type of Device | Comments |
|---|---|---|---|
| 1953[1] | Gibbon | Heart–lung machine | Closure of ASD in human |
| 1959[2] | Spencer | Femoral bypass | First case of successful recovery postcardiotomy |

without expected recovery of myocardial function, but who are not candidates for cardiac transplantation due to older age, obesity, smoking, cancer, pulmonary hypertension, social concerns, or other advanced organ dysfunction. Longer term support devices intended for extended treatment periods are utilized for this purpose, and this is currently the second most common indication for device implantation today.

**Device strategy at time of implant of primary LVAD (INTERMACS: June 2006–March 2009)**

the third-generation centrifugal pumps, and TAHs.[10] Some FDA-approved devices are listed in Table 51-3.

## Early Devices

Early devices for MCS were easy to insert, relatively inexpensive, and the most easily available of the assist devices. They have been designed for short-term support lasting hours to days, and are most often employed for postcardiotomy failure.

### NONPULSATILE, CENTRIFUGAL/ROTODYNAMIC RADIAL FLOW PUMPS

Blood flow for these devices is generated by rotating blades or impellers.[11] These devices do not have valves or multiple moving or occluding parts (Fig. 51-2), theoretically reducing the potential for hemolysis. These devices require priming with volumes differing from pump to pump (52–87 mL).

**FIGURE 51-2** BioMedicus (Medtronic Inc.) Centrifugal pump. (Copyright 2010 Medtronic, Inc.)

Devices of this class are capable of providing high flow rates with low rises in pressure. Several commercial devices are available, including the Carmeda Bio-Pump and the BIO-PUMP (Medtronic Inc, Minneapolis, MN), the Sarns pump (Terumo Cardiovascular Systems Ann Arbor, MI), and the Nikkiso pump (Nikkiso Pumps America Inc., Plumsteadville, PA). These devices are not designed for long-term use. Indications include left heart bypass for thoracic aortic surgery, postcardiotomy ventricular failure, extracorporeal membrane oxygenation (ECMO), and bridge to transplantation or to another VAD. Cannulation sites commonly used for left heart bypass include the left superior pulmonary vein or left atrium (inflow) and the ascending aorta or femoral artery (outflow). For right heart bypass, inflow is obtained via right atrial cannulation with outflow directed into the pulmonary artery. Cannula fixation is important with these and other devices, since most hemorrhagic complications are due to cannula dislodgement. Anticoagulation is required after device insertion and must be monitored closely.

There are no firm criteria for device weaning and removal, but the achievement of hemodynamic stability and a documented cardiac recovery dictate the removal strategy. Typically a gradual reduction in support is initiated over hours to days with device removal once minimal support is required. When a device of this class fails, it is often due to breakdown of the pump head seal, leading to the entry of fluid into the magnetic chamber.[12] Clinical experience has shown that these pumps are especially well suited for left heart bypass and for short-term postcardiotomy left ventricular failure. In one study, 62 patients were supported using the centrifugal pump for postcardiotomy failure; 22 patients required left ventricular support, 9 required right ventricular

support, and 31 required biventricular support. Support was extended for up to 19 days, with 42 patients weaned successfully, 27 patients discharged home, and 18 patients surviving more than 1 year.[13] Other studies have reported similar results for short-term support.[14,15]

## PARACORPOREAL PULSATILE DEVICES

***Abiomed BVS 5000.*** This device was approved by the FDA in 1992 for use in all types of recoverable heart failure. It is an external pulsatile VAD capable of supporting the right and/or left ventricles for days to weeks. This device is a pneumatically driven, asynchronous, pulsatile, automated, self-regulating, polycarbonate-housed dual-chamber pump system (Fig. 51-3). The atrial chamber of this two-chamber pump fills passively by gravity drainage; the volume is usually about 100 mL, and the internal chamber is made of flexible polyurethane. The atrial chamber drains into the ventricular chamber through a trileaflet valve made of proprietary material. During systole, compressed air is delivered into the ventricular chamber; it compresses the polyurethane bladder and ejects its contents toward the patient. The pumping unit and console are located outside the body; the inflow and outflow cannulas are tunneled subcutaneously into the mediastinum. Each pump is capable of delivering a maximal output of 6 L/min at a constant stroke volume of 80 mL.

The implantation technique for the BVS 5000 varies from center to center. For right ventricular support, the inflow cannula is placed into the mid-right atrium and secured firmly with pledgeted purse-string sutures. Another alternative is to insert this cannula directly into the right ventricle through its diaphragmatic surface, particularly if there are adhesions from previous surgery. The outflow cannula is anastomosed to the main pulmonary artery. For left ventricular support, the inflow cannula is placed into the left atrium via the right superior pulmonary vein, left atrial dome or directly into the left ventricle via the apex. Left ventricular apical cannulation permits complete ventricular decompression, optimizing its chance for recovery. Left ventricular apical cannulation is also advantageous if a mechanical mitral prosthesis is in place, since it permits opening and closing of the leaflets and may reduce thrombotic complications. The outflow cannula is anastomosed to the ascending aorta.

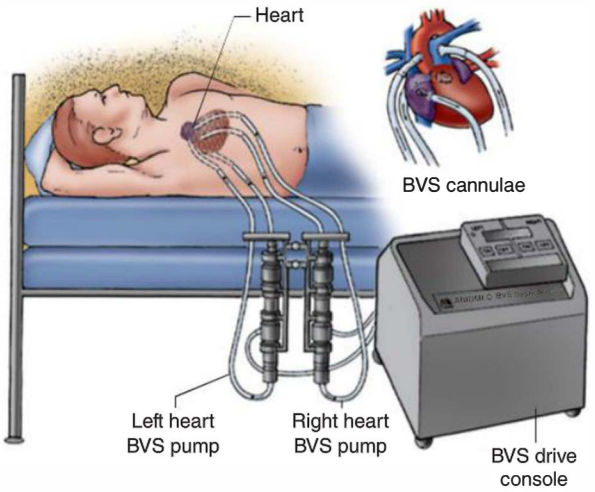

**FIGURE 51-3** Abiomed BVS 5000. (With permission from ABIOMED Inc.)

Heparin anticoagulation is required during BVS 5000 support and must be closely monitored; an activated clotting time (ACT) of 180 to 200 s is the goal. The pump is easy to manage and operated based on the principles of preload and afterload management. Limitations of this device include limited patient mobility, restricted flow capacity, and heparinization requirements.

A prospective multicenter trial evaluated the safety and efficacy of the BVS 5000 in 31 patients with hemodynamic instability despite maximal pharmacologic and IABP support. There was an improvement in mean arterial pressure from 50.1 ± 15.3 mm Hg prior to support to 77.1 ± 8.0 mm Hg after support was initiated ($p$ <0.01). The cardiac index increased from 1.6 ± 0.6 L/min/m$^2$ before support to 2.3 ± 0.3 L/min/m$^2$ after support was initiated ($p$ <0.01). A total of 76 percent of the cohort (42 patients) experienced bleeding; 17 (55 percent) were successfully weaned from support, and 9 (29 percent) were discharged.[16]

In a retrospective review, the BVS 5000 was implanted in 47 patients exhibiting postcardiotomy acute heart failure. There were 38 patients in the BTR group and 9 in the BTT group. A total of 25 patients (66 percent) in the BTR group were weaned, and 16 patients (42 percent) went on to discharge. In the BTT group, 1 patient recovered myocardial function and 1 died while awaiting transplantation, although 7 patients (77 percent) underwent successful cardiac transplantation with a posttransplant survival rate of 66 percent. Patients were supported in the isolated left ventricular (28 percent), biventricular (45 percent), and right ventricular modes (28 percent).[17] In a more recent study involving 202 patients, survival at 3 days, 30 days, and 5 years was 76, 38, and 24 percent, respectively. Patients surviving 30 days experienced a 63-percent 5-year survival. A total of 48 patients (21 percent) were bridged to transplantation, and 71 patients (35.5 percent) were weaned with intent for survival.[18] Similar results are reported from other centers.[19] The wean and discharge rates is generally around 60 and 40 percent, respectively, and this approach has been shown to be cost-effective as well.[20]

***Abiomed AB5000.*** The next-generation device to follow the BVS 5000 was the Abiomed AB5000 (Fig. 51-4). This device was an updated, improved version of the BVS 5000. This pneumatically driven device utilizes the same cannulas as the BVS 5000, allowing an easy transition to this device. The AB5000 provides flows up to 6 L/min and is capable of right- or left-sided support and has a console that enables patients to become mobile within the hospital setting.

The experience with transition from BVS5000 to AB5000 in the same patient has also been good. A report of 50 patients

AB5000 Ventricle

AB5000 Console

**FIGURE 51-4** Abiomed AB5000. (With permission from Abiomed Inc.)

who initially underwent BVS5000 implantations at primary hospitals who were then transferred to tertiary care centers and were converted to the AB5000 device reported a 42 percent survival rate to either recovery, DT implantation, or transplant.[21] Of the surviving 21 patients, 18 were alive 30 days after device removal with 61 percent able to be weaned, 5.6 percent receiving a DT device, and 33 percent proceeding to transplantation.

The initial published experience with primary device implantation in patients with AMI and hemodynamic instability or postcardiotomy shock was encouraging with several patients able to be weaned from their support prior to successful hospital discharge.[22] A more recent report from the national AB5000 device registry among 100 patients who underwent AB5000 implantation for cardiogenic shock following AMI demonstrated a 40 percent 30-day survival with 63 percent successfully weaned from support, 17 percent transitioned to another support device, and 20 percent proceeded to transplantation. Of those who achieved myocardial recovery and device explantation, 2-year survival was 78 percent.[23]

## First-Generation, Pulsatile Devices

The first-generation devices have a pulsatile mode of action with flow originating from a pumping chamber separated by two valves, one for inflow and another for outflow. These are pneumatically or electrically driven and have a cyclical mode of filling and emptying.

### THORATEC VAD

The Thoratec VAD (Thoratec, Pleasanton, CA) was approved by the FDA in 1996 for use for BTT and subsequently in 1998 for BTR; this is the only approved dual-use device on the market. It was first used clinically in 1982 for postcardiotomy failure. Initially labeled the Thoratec VAD, with the subsequent development of the Thoratec implantable VAD (iVAD), this device became known as the Thoratec paracorporeal VAD (pVAD) and will be further referred to as such.

The Thoratec pVAD device is flexible and can be employed for short- or long-term use in both large and small patients because of its paracorporeal design. It is a pneumatically driven paracorporeal pump that uses Delirin tilting monostrut mechanical disk valves for maintaining unidirectional blood flow (Fig. 51-5). There is a flexible blood sac housed in a rigid outer casing; this sac is compressed by air to achieve ejection. Separate pumps are needed for each side of the heart. Three modes of operation are available: fill-to-empty, fixed-rate, and electrocardiogram (ECG)-synchronous modes. The most commonly used mode is the fill-to-empty mode, which pumps at a rate determined by VAD filling. The inflow and outflow cannulas being the only internal components, this pump can be used for small patients, including children. The cannulas are made of polyurethane except for the distal part,

**FIGURE 51-5** Thoratecparacorporeal VAD. (Reprinted with the permission of Thoratec Corporation.)

which is made of polyester Dacron. Usually CPB is needed for implantation of the cannulas. For left ventricular support, inflow can be achieved via the left ventricular apex or the left atrium; outflow is usually to the ascending aorta. For right heart support, inflow is via the right atrium and outflow is directed into the main pulmonary artery. Proper positioning of the cannulas is essential for reducing undue kinking of the cannulas and optimal device positioning on the abdominal wall. Anticoagulation with heparin followed by warfarin is required. The main limitations of this device include rather bulky paracorporeal pumping chambers and restricted patient mobility due to a large drive console.

More than 4000 patients have undergone Thoratec pVAD device implantation for left, right, and biventricular support with the longest duration of support of 1204 days. This device has been particularly useful for short-term BTT in patients suffering from biventricular failure.[24] In an analysis of 828 BTT patients, this system was used for biventricular support in 472 cases, left ventricular support in 326 cases, and right ventricular support in 30 cases for up to 515 days. During the support periods, cardiac indices increased significantly from $1.4 \pm 0.8$ to $3.0 \pm 0.5$ L/min/m$^2$ (with biventricular assistance and left ventricular cannulation). Of the 828 patients, 60 percent underwent transplantation, and the posttransplant survival rate was 86 percent. In the 195 patients who needed postcardiotomy support, the device was used for up to 80 days for cardiac recovery. Thirty-eight percent of the patients were weaned from the device, with 59 percent of these patients discharged. Of 49 postcardiotomy patients considered for transplantation, 32 underwent transplantation and 23 were discharged. Other series reflect similar results.[25,26]

Newer series also validate the earlier experiences with the pVAD. Among 84 patients who underwent pVAD implantation, 56 percent were able to wean from support or proceed to transplantation with actuarial survivals of 79, 73, and 63 percent at 1, 3, and 5 years after device implantation.[27] Another recent series with 71 patients with a total of 5193 patient-days of support had 65 percent of patients either bridged to recovery or to transplantation with actuarial survivals of 76, 68, and 62 percent at 1, 2, and 3 months, respectively.[28]

An experience with a new portable drive unit designed to allow home discharge demonstrated excellent clinical outcomes with an average discharge time of 62 days (range 16–242) and 89 percent of patients surviving to myocardial recovery and device explantation or transplantation.[29] The majority of postimplantation time (83 percent) was outpatient with significant improvement in CHF symptoms to NYHA I or II following device implantation.

Use of the pVAD for biventricular support has also been examined. Among a series of 73 patients who had ThoratecpVAD implanted as both right ventricular assist device (RVAD) and LVAD, 84 percent went on to transplantation, 10 percent were weaned and had successful device explantation, and 6 percent remained with BIVAD support.[30] Overall survival was 69 percent and 5-year survival for those receiving a heart transplant was 58 percent. For patients with high likelihood of right ventricular failure after LVAD implantation, the decision to perform both RVAD and LVAD implantation at the same time leads to improved outcomes compared with delayed BIVAD implementation.[31] Among 99 patients who underwent Thoratec BIVAD placement, there was a trend toward improved bridging to transplantation (65 vs 45 percent, $p = 0.10$) and a significantly improved survival to discharge (51 vs 29 percent, $p < 0.05$) among patients with immediate BIVAD placement compared with those who underwent delayed RVAD implantation after initial LVAD implantation. In a separate study, risk factors for eventual need of RVAD following LVAD placement included cardiac index <2.2 L/min/m$^2$, RV stroke work index <0.25 mm Hg · L/m$^2$, severe preoperative RV dysfunction, preoperative creatinine >1.9 mg/dL, reoperative cardiac surgery, and systolic blood pressure <96 mm Hg.[32]

In 2004, the FDA licensed the Thoratec iVAD for BTT, with identical features to that of the pVAD but with an intracorporeal placement (Fig. 51-6). Results from two groups have been published.[33,34] Slaughter et al. reported 39 patients who underwent placement of the iVAD who were supported for 3938 patient-days. This group was compared with a historical group of 100 patients who underwent implantation of the Thoratec pVAD device. Survival outcomes were similar for both iVAD and pVAD for BTT (70 vs 69 percent survival to transplantation) and slightly better for BTR (67 vs 48 percent survival to explant and myocardial recovery) indications, respectively. Berman et al. reported 24 patients who were supported for 2308 patient-days.[34] Survival to transplantation was 71 percent in this cohort. Taken together, these results suggest that the Thoratec iVAD has results similar to the pVAD with the advantages of its intracorporeal position. To date, more than 500 patients have undergone implantation of the iVAD device with the longest duration of support of 979 days.

## HEARTMATE LVAD

The HeartMate LVAD (Thoratec Corp., Pleasanton, CA) was designed in 1975 as an implantable, pulsatile, pneumatically actuated (HeartMate IP), intracorporeal left ventricular assist system.[35] The pneumatically driven unit is made of sintered titanium and houses a flexible, textured polyurethane

**FIGURE 51-6** Thoratecintracorporeal VAD. (Reprinted with the permission of Thoratec Corporation.)

FIGURE 51-7 HeartMate IP VAD. (Reprinted with the permission of Thoratec Corporation.)

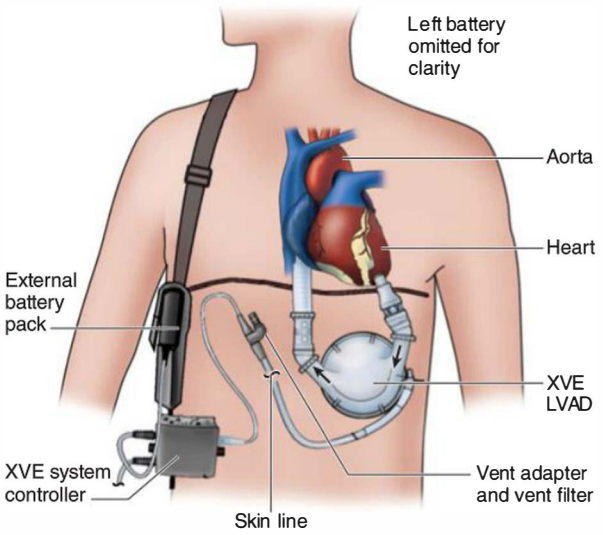

FIGURE 51-8 HeartMate XVE VAD. (Reprinted with the permission of Thoratec Corporation.)

diaphragm. It is driven by a pusher-plate mechanism that, in turn, is driven by compressed air and controlled by a console (Fig. 51-7). The design was modified to a vented electrical system (HeartMate VE) in 1991 with a much smaller console, which confers greater patient mobility.[36] The inflow and outflow conduits utilize porcine xenograft valves (Medtronic-Hancock, Minneapolis, MN). The maximum stroke volume generated is about 85 mL and maximum output can reach up to 11 L/min. The blood-contacting surfaces, unlike those of other devices, are made up of textured polyurethane, which facilitates deposition of a fibrin-collagen matrix, forming a pseudointimal layer. This feature eliminated the anticoagulation requirement, calling for aspirin only. To accommodate the device, the patient's body surface area (BSA) must to be at least 1.5 $m^2$. The pump is inserted either pre- or intraperitoneally in the left upper quadrant of the abdomen. There are two modes of operation: fixed mode (20–140 bpm for IP and 50–120 bpm for VE) and automatic mode. In the latter mode, the pump senses when its chamber is full and activates the pusher-plate mechanism (fill-to-empty). The battery life usually ranges from 4 to 6 h, with a portable hand pump backup available for device malfunction or power failure. Following the successful REMATCH trial, the enhanced version of the HeartMate SNAP-VE, the HeartMate XVE LVAS, was approved by the FDA for DT in 2002 (Fig. 51-8). The notable modification was the inflow valve conduit, which was designed to be six times more durable than in previous versions. To date, more than 1300 patients have undergone HeartMate IP LVAS implantation, although close to 2500 patients have received the HeartMate VE LVAS, with cumulative patient-years of 330 and 964 years, respectively. Over 4500 patients have received the newest HeartMate XVE device with the longest duration of support of 1864 days.

Experience from Columbia University of 243 patients undergoing implantation of HeartMate devices included 52 pneumatic, 17 dual-lead vented electrical, and 174 single-lead vented electrical devices. Overall actuarial survival rates at 1, 3, 5, and 10 years posttransplant were 90.5, 85.1, 69.6, and 39.6 percent, respectively. The overall incidence of infection was 17.7 percent ($n = 43$). Device malfunctions occurred in 32 patients.[37,38] A pivotal prospective multicenter clinical trial was conducted at 24 centers in the United States. There were 280 transplant candidates (232 men, 48 women; median age 55 years) unresponsive to inotropic drugs, intraaortic balloon counterpulsation, or both who received the device. These patients were compared with a control group of 48 patients who were not supported with a device. HeartMate VE support lasted an average of 112 days, with 54 patients supported for more than 180 days. Device-related adverse events included bleeding in 31 (11 percent), infection in 113 (40 percent), neurologic dysfunction in 14 (5 percent), and thromboembolic events in 17 (6 percent) of patients. Successful BTT was observed in 71 percent of HeartMate patients, compared with 33 percent of the control group ($p < 0.001$). A total of 198 patients survived, with

188 patients undergoing cardiac transplantation. One-year survival after transplantation was significantly better in patients who underwent LVAD implantation compared with the control population [84 percent (158 of 188) vs 63 percent (10 of 16); log rank analysis $p = 0.0197$)].[39]

A more recent report by Long et al. compared 42 patients who underwent HeartMate XVE implantation to those who received HeartMate VE devices from the REMATCH trial.[40] This study showed that there was improved survival with the newer HeartMate XVE compared with the VE (30 day: 90 vs 81 percent, 1 year: 61 vs 52 percent), as well as a decrease in adverse events. Whether the improvement in outcome was due to the advancements in technology or an improvement in patient selection and postoperative care is not known. Despite these outcomes, the HeartMate XVE has had issues with durability with device exchange or failure of 18 and 73 percent at 1 and 2 years, respectively.[38]

## NOVACOR LVAS

The Novacor LVAS (World Heart Corp., Ottawa, Canada) was developed in collaboration with Stanford University and was originally planned as a totally implantable system. It was the first device to bridge a patient successfully to transplant in 1984.[41] Over the years it evolved into a console-based VAD. The pump drive unit incorporated a dual pusher-plate sac-type pump with a smooth blood-contacting surface. The stroke volume was about 70 mL. It had two porcine-valved polyester inflow and outflow conduits. The system had a high-efficiency linear motor using a pulsed solenoid energy converter with a two-armature assembly. Thus it required no gears, cams, or intermediate hydraulic conversion, reducing the potential for mechanical failure. There were three modes of operation: single-stroke, fixed-rate, and automatic or synchronous (fill-to-empty) modes. The pump filled passively, aided by the large circular dual-pusher-plate surface area (Fig. 51-9). The power packs had 6 h of work life and could be worn on a belt, vest, shoulder bag, or backpack. Anticoagulation with warfarin was necessary and was closely monitored. The primary cause of mechanical failure was wearing out of the energy converter, although this usually was detected at least 3 months prior to its ultimate failure.[42]

The Novacor LVAS was successfully used for the past two decades as a bridge to cardiac transplantation in patients with end-stage congestive heart failure. Stanford University reported a series of 53 Novacor patients (48 male, 5 female) with a mean age of 44 years (range of 16–62 years) and a mean support time of 56 days (range of 1 to 374). Complications consisted of bleeding (43 percent), infection (30 percent), and embolic cerebrovascular events (24.5 percent). Sixty-six percent of the supported patients were successfully bridged to cardiac transplantation.[43] A recent study suggested that, in terms of durability, the Novacor device exceeded the HeartMate VE at 2 months (93.5 percent). Novacor's durability at 3 years was 85.9 percent, with 78 percent of supported patients surviving to transplantation.[44] Another study reported improvement in cardiac output, wedge pressure, pulmonary vascular resistance, and mean pulmonary pressure after Novacor implantation. Most of the complications observed were related to thromboembolism and occurred in the first 3 months after implantation.[42]

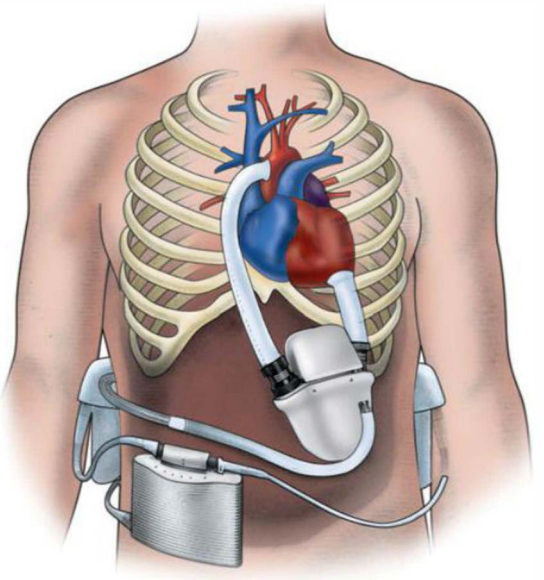

**FIGURE 51-9** Novacor VAD. (With permission from HeartWare International (for World Heart Corporation), Framingham Mass.)

The Novacor was discontinued in 2008 with later-generation devices from the same manufacturer (Levacor LVAD) taking its place.

## LIONHEART LVAS

Developed at Penn State University, the LionHeart LVAS (Arrow International, Reading, PA) was specifically designed for DT in patients with end-stage chronic heart failure.[45] The system was fully implantable without any external conduits for power. This was the first system to not require a percutaneous driveline and gave hope to the eventual development of a totally implantable device. It utilized a brushless motor that actuated a pusher plate using a roller-and-screw mechanism and Delirin disk monostrut valves. The blood-contact surfaces consisted of polyurethane sacs, which filled passively. The stroke volume was approximately 65 mL and the maximum achievable flow rates were 8 L/min. The LionHeart required a gas-filled compliance chamber implanted in the left pleural space to accommodate pump volume displacement (Fig. 51-10). In addition, there was a subcutaneous infusion port that was replaced every 2 to 4 weeks. The battery and system controller were all implanted in the right lower quadrant of the abdomen. The LionHeart's pumping characteristics, based on end-diastolic volumes, were automatically adjusted by a software algorithm, which attempted

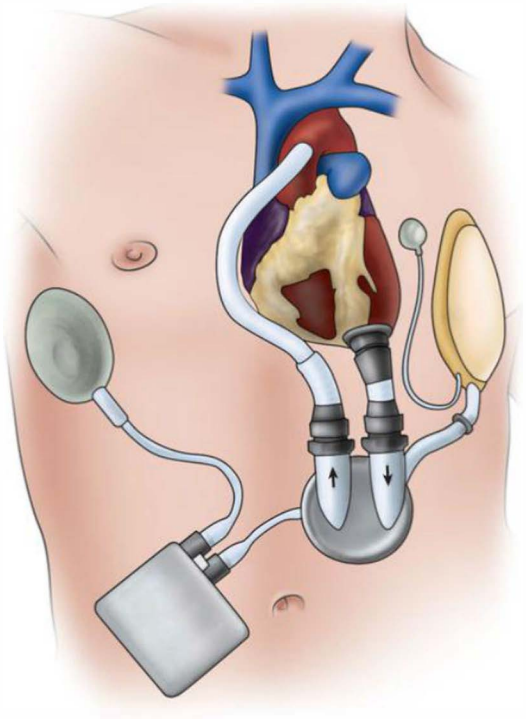

**FIGURE 51-10** Arrow LionHeart. (With permission from Arrow International.)

to provide maximal filling of the pump with each stroke by altering pump speed. The unique feature of this LVAS system was the transcutaneous energy transmission system (TETS), in which electrical energy was supplied to the pump's drive unit by radiofrequency induction. Warfarin anticoagulation was required with this device.

The first clinical implantation of the LionHeart was performed in 1999; the first implantation in the United States was performed in 2001.[46] The Clinical Utility Baseline Study (CUBS) was designed to determine the safety and performance of the LionHeart LVAS to serve as a permanent mode of circulatory support for patients with end-stage heart failure who were ineligible for heart transplantation. As a part of this trial, 26 male patients underwent implantation at seven European Centers; actuarial survival rates were 86 percent at 1 month, 45 percent at 6 months, 41 percent at 1 year, and 34 percent at 2 years.

The LionHeart LVAS was discontinued in 2005 by the manufacturer in favor of development of the newer CorAide device.

## Second-Generation, Rotary Axial Pumps

The second-generation mechanical circulatory assist devices sought to improve upon the design of the first-generation

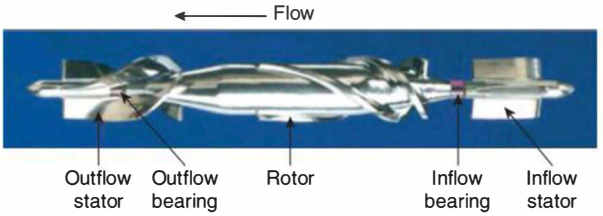

**FIGURE 51-11** Second generation axial flow pump design. (Figure courtesy of Thoratec Corporation.)

devices and to address some of the potential complications with the earlier technology. These are smaller, valveless, implantable devices that provide continuous axial flow (Fig. 51-11). An internal rotor suspended by contact bearings within the device is electrically driven by an external power source.

The first-generation pulsatile LVADs are hampered by percutaneous drivelines and bulky consoles and support systems. In addition, these assist devices are generally not suitable for patients with body surface areas of less than 1.5 $m^2$ or in pediatric patients with the exception of the ThoratecpVAD. Other characteristics of these devices include bleeding complications and difficulty in explantation. These limitations prompted the development of axial flow pumps. Technically, nonpulsatile flow pumps are more attractive than pulsatile systems because they have one moving part, permitting compactness in design, ease of insertion, and lower energy consumption. These devices are inserted into the ventricular apex (inflow) and anastomosed to the thoracic ascending or descending aorta (outflow). They do not require valves and compliance chambers, affording additional simplicity. Despite these advantages, several potential drawbacks exist. Device failure could potentially result in significant backflow of 1.5 to 2.0 L/min from the aorta into the left ventricle. Also, blood-washed bearings were not studied prior to the HeartMate II experience to adequately determine thrombogenic potential and wear characteristics. Early research showed little bearing wear and a reasonable thrombogenicity profile.[47] Furthermore, earlier concerns about the nonphysiologic nature of nonpulsatile blood flow persists, although results from rotary axial flow pumps have been encouraging. Table 51-4 summarizes the clinical data available for the second-generation devices.

### DEBAKEY VAD

The DeBakey VAD (MicroMed Technology Inc., Houston, TX) resulted from a collaboration between the Baylor College of Medicine and NASA; it is undergoing clinical trials in United States and European centers.[48,49] A small (30-mm diameter, 76-mm length, 95-g weight) titanium axial flow pump, the DeBakey VAD is based on an axial impeller–inducer supported by an inflow straightener and outflow diffuser housing ceramic blood-lubricated bearings. The pump produces a flow of 5 to 6 L/min and generates a

**TABLE 51-4: Clinical Data from Second-generation Devices**

| Device | Reference | Year | Patients | Indication (Patients) | Average Support (Days) | Longest Support (Days) | Patients Transplanted (%) | Overall Survival (Time) | Bleeding (%) | Infection (%) | Thrombosis (%) | Mechanical Pump Failure (%) | RV Failure (%) | RVAD Placement (%) |

pressure of 100 Torr at 10,000 rpm. An ultrasonic flow probe continuously measures the pump output. The inflow cannula is placed in the left ventricular apex and the outflow cannula can be anastomosed to the ascending or descending aorta. The pump is placed in a small preperitoneal pocket. A percutaneous driveline connects the power supply and control to the pump from an external console. Pump flow is nonpulsatile and requires warfarin anticoagulation. Laboratory indices reveal no significant hemolysis or changes in plasma free hemoglobin.

Worldwide experience with the DeBakey VAD includes 150 patients who underwent placement of the device as a BTT. In this series, 82 patients (55 percent) were bridged to transplantation/recovery or are currently supported and 68 patients (45 percent) died with the device.[50] Reoperation for bleeding was the most common adverse event in 48 patients (32 percent), followed by hemolysis (12 percent) and device infection (3.3 percent). Device failure occurred in four cases. Seventeen pumps (11 percent) were noted to have detectable thrombus; of these, eleven cases (64 percent) were successfully resolved with transplantation, pump exchange, or thrombolysis. Thromboembolic events occurred in 10.7 percent of patients. There is currently an ongoing clinical trial for DT (DELTA: Destination Evaluation Long-Term Assist) using the DeBakey VAD and Thoratec HeartMate XVE.

## FLOWMAKER (JARVIK 2000)

The Jarvik 2000 (Jarvik Heart Inc., New York, NY) is a titanium axial flow pump (25 mm diameter, 51 mm length, 90 g weight) that is implanted in the left ventricular apex. The outflow graft is anastomosed to either the ascending or the descending aorta depending on the surgical approach (Fig. 51-12).[51] The pump can be implanted by either a sternotomy or a thoracotomy, and with or without cardiopulmonary bypass. The lack of a pump pocket and the use of a unique postauricular connector that brings power through the infection-resistant scalp tissue behind the ear has reduced infection to less than 5% with infection rate of only .03 events/patient year. The Jarvik 2000 is available for BTT under a CAP approval and is used in a randomized destination therapy trial approved for 350 patients at up to 50 U.S. medical centers. It has CE mark and is available throughout Europe.

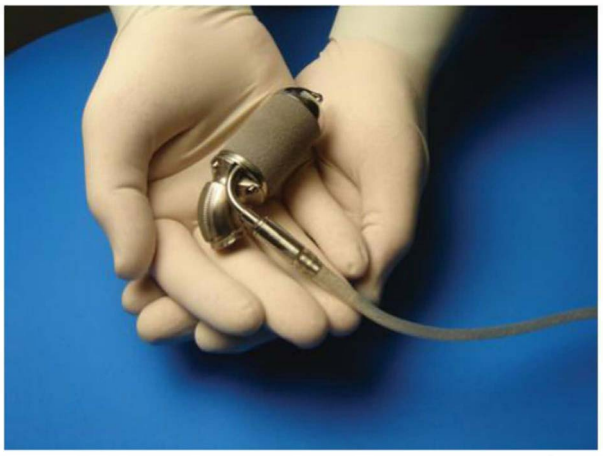

**FIGURE 51-12** The Flowmaker. (Jarvik 2000, with permission from Jarvik, Inc.)

Three different options are available for energy transmission: a percutaneous lead, a skull-mounted titanium pedestal, and Transcutaneous Energy Transfer and Telemetry System (TETTS).[51] The Flowmaker is capable of producing flows of 7 L/min at 8000 to 12,000 rpm and requires warfarin anticoagulation. Pump flow rates can be adjusted manually in times of increased activity or can be set at a fixed rate.

The first patient to receive a Flowmaker was a 61-year-old with dilated cardiomyopathy and NYHA class IV heart failure who was implanted in 2000 for DT.[52] This patient was alive and was highly functional with an improvement to NYHA class II heart failure 6 years after implantation.[53]

Frazier et al. described the experience of 26 patients who underwent implantation of a Jarvik 2000 device for BTT (22 patients) or DT (4 patients).[54] In this series 13 patients (55 percent) underwent successful transplantation after a mean support of 67 days.

Since these early reports, over 100 patients have been implanted with this device internationally.[55] Siegenthaler reported on a multicenter (European and American) experience in 102 patients who were implanted as BTT (83 patients) or DT (19 patients). There were no mechanical device failures either during in vivo use or in ex vivo bench testing over a total of 110 cumulative years (59 years in vivo, 51 years ex vivo). Mean device support times for BTT and DT were 159 and 551 days, respectively. Six of the 19 DT patients were alive for greater than 2 years and one patient nearly 5 years after implantation. The Flowmaker may prove to be a reliable, long-term solution for DT and a viable solution for BTT in appropriate patients.

## HEARTMATE II

The HeartMate II (Thoratec Corp., Pleasanton, CA) was born out of research conducted at the University of Pittsburgh in collaboration with Nimbus and has been one of the most studied devices to date. It received FDA approval for DT in 2010. It has a 40-mm diameter, 70-mm length, 176-g weight.[56] The pump mechanism is similar to that of the DeBakey VAD and Jarvik 2000. It is capable of achieving flow rates of 10 L/min and can generate 120 Torr of aortic pressure, operating at 6000 to 13,000 rpm (Fig. 51-13). The pump receives its inflow via the left ventricular apex and delivers outflow to the ascending aorta; it is placed in a small preperitoneal pocket. The current system uses a percutaneous driveline to supply power and control from an external console. Patients are maintained on warfarin anticoagulation and aspirin therapy. The first human implant was performed in 2000, and since then, the device has been evaluated by many groups.[57] The ease of implantation, small size, and nonpulsatile flow

**FIGURE 51-13** HeartMate II. (Reprinted with the permission of Thoratec Corporation.)

has made this a popular device, and results from both single institution experiences and multicenter clinical trials have established the HeartMate II as an effective device for MCS, which has revolutionized modern LVAD therapy.

Miller et al. reported the results of their prospective, multicenter clinical trial with the HeartMate II among 133 patients who received device implantation as BTT.[58] One hundred patients went on to transplantation (56 patients), continued support (43 patients), or device explantation due to myocardial recovery (1 patient). Among these patients, median device support was 126 days with an 89-percent 1-month, 75-percent 6-month, and 68-percent 1-year survival. Following successful transplantation 94 percent of patients were alive at 1 month, and 80 percent at 1 year. Heart failure was improved on device therapy as measured by both quantitative and qualitative measures. Six-minute-walk tests increased from a mean of 42 m at baseline to a mean of 292 m after 3 months of device therapy. Both the Minnesota Living with Heart Failure and Kansas City Cardiomyopathy questionnaires were statistically significantly improved at this time point as well. The most frequent complication was bleeding with 53 percent requiring transfusions greater than two units in the postoperative period and 31 percent who required re-exploration for control of hemorrhage. Rates of both for ischemic (6 percent) and hemorrhagic (2 percent) stroke were low. Rates of infection were also low with device-related infection of only 14 percent, and nondevice related infection of 28 percent. Leading causes of death were stroke (6 percent), sepsis (4 percent), and multisystem organ failure (3 percent). Rates of right heart failure were 17 percent and pump thrombosis 2 percent. Two patients who required device replacement were alive at 216 and 367 days after replacement.

In a follow-up to this trial, Pagani et al. reported the HeartMate II Investigators' extended experience among 281 patients who underwent implantation of the HeartMate II as a BTT.[59] Again, there were improvements in heart failure following 6 months of therapy; 6-min-walk test was completed in 83 percent compared with 0 percent at baseline and NYHA heart failure improved from 0 percent class I or II at baseline to 83 percent. Overall survival at 18 months was 72 percent, with 56 percent of patients undergoing transplantation, 21 percent continuing on device support, and 3 percent who experienced myocardial recovery. Again, the most common adverse event was bleeding in 53 percent, and mediastinal re-exploration in 26 percent. Infection was the next most common with nondevice infection in 30 percent, device infection in 14 percent, and sepsis in 17 percent. Stroke rates were low at 8 percent (5 percent ischemic, 3 percent hemorrhagic). Right heart failure was 17 percent and pump thrombosis was only 1 percent.

Another trial reported by the HeartMate II investigators was for use of this device as DT among patients with advanced heart failure.[60] This trial compared the nonpulsatile HeartMate II and the older-generation, pulsatile HeartMate XVE. Patients with advanced heart failure refractory to maximal medical support and who were ineligible for cardiac transplantation were included. Patients with significant pulmonary, hepatic, or renal dysfunction were excluded. The primary endpoint was survival at 2 years without stroke or reoperation for device exchange. Secondary endpoints included actuarial survival, adverse events, functional status, and overall quality of life. The HeartMate II demonstrated a clear improvement in outcome compared with the HeartMate XVE with regard to the primary endpoint (46 vs 11 percent at 2 years). In addition, events that prevented patients from reaching the primary endpoint such as reoperation to repair or replace the pump (10 vs 36 percent) or any reason overall (54 percent vs 89 percent) were statistically different among the HeartMate II and HeartMate XVE groups, respectively. Actuarial survival rates at 1 and 2 years were significantly better with the HeartMate II than the HeartMate XVE as well; 68 percent vs 58 percent and 55 vs 24 percent, respectively, among the groups.

Both groups experienced improvements in NYHA class heart failure, increased performance on the 6-min-walk test, and improved quality of life following device implantation. At baseline, all patients had severe heart failure, including 75 percent who had NYHA class IV heart failure in the HeartMate II group and 78 percent in the HeartMate XVE group. For the HeartMate II group, after 12 months of device support 76 percent of patients were improved to NYHA class I or II, and by 24 months 80 percent of patients were improved to NYHA class I or II heart failure in 42 percent and 38 percent, respectively. In the HeartMate XVE group after 12 months, 61 percent were improved to NYHA class I or II, and by 24 months the remaining surviving patient had NYHA class I heart failure. Six-minute-walk times were improved from a mean of 182 to 372 m for the HeartMate II group and from 172 to 306 m for the HeartMate XVE group. Results from both the Minnesota Living with Heart Failure and Kansas City Cardiomyopathy questionnaires were also significantly improved from baseline, the former

being statistically better with the HeartMate II and the latter approaching significance between the groups.

Rates of adverse events with the HeartMate II were also significantly decreased compared with the HeartMate XVE, including both device and nondevice infection, right heart failure, arrhythmias, and respiratory and renal failure. The leading causes of death were hemorrhagic stroke (9 vs 10 percent) and right heart failure (5 vs 8 percent) in both groups, HeartMate II and XVE, respectively. Bleeding requiring transfusions occurred in 81 and 76 percent and that requiring re-exploration in 30 and 15 percent among the HeartMate II and HeartMate XVE, respectively. Pump thrombosis was more common in the HeartMate II group at 4 percent, compared with no patients in the HeartMate XVE group.

Frazier et al. reported the Texas Heart Institute experience with the HeartMate II in 43 patients, 23 for BTT and 17 for DT.[61] In this initial experience, the average support time was 258 days and 35 survived to hospital discharge including 3 patients who underwent transplantation and 4 patients who had myocardial recovery and pump explantation. Ongoing support was reported in 27 patients with the longest greater than 700 days. Cardiac index was significantly improved and pulmonary capillary wedge pressures were reduced in all patients, and inotropes were removed by 1 week following implantation. All patients improved to NYHA class I status following implantation. There were 9 deaths; 5 died from multifactorial causes (multisystem organ dysfunction, right heart failure, and hemorrhage) and two patients suffered strokes.

John et al. reported an experience in 47 patients who received the HeartMate II for BTT (32 patients), DT (7 patients), or exchange for a prior device (8 patients) demonstrating excellent results: 96-percent 30-day and 87-percent 6-month survival among patients receiving a HeartMate II and mean support time of 193 days with a 3-percent incidence of device malfunction.[62] Among those patients who received a HeartMate II for BTT, 60 percent were transplanted and all survived to discharge. Renal and hepatic function were both significantly improved after 3 months of device therapy. The most common complications were bleeding in 32 percent, half of whom required re-exploration, followed by infection in 13 percent. Right ventricular failure and pump thrombosis were uncommon, each occurring in 6 percent of patients. Stroke was equally uncommon, occurring in only 6 percent of patients.

Lahpor et al. reported the European experience among three centers and 571 patients implanted as BTT (73 percent), DT (21 percent), and BTR (6 percent).[63] Mean support was 236 days with support greater than 6 months, 1 year, and 2 years of 61, 29, and 3 percent, respectively. Survival at 6 months was 74 percent and at 1 year was 72 percent. In this group, 23 percent proceeded to transplantation, 42 percent have continued support, and 4 percent underwent device explantation following myocardial recovery. The most frequent cause of death was multifactorial in nature (sepsis, right heart failure, followed by stroke). Bleeding occurred in 51 percent and was not a source of mortality. There were only three device thromboses, and right heart failure occurred in 20 percent.

Loforte et al. reported the Italian experience with the HeartMate II among their 18 patients who underwent implantation for BTT.[64] In this group, the median support time was 217 days with the longest supported patient having continued support 665 days after implantation. Fifty percent of patients proceeded to transplantation with 67 percent alive after transplantation at last following. There were no device failures, and the most common complications were bleeding in 33 percent, right ventricular failure in 28 percent, infection in 11 percent, and thrombosis in 6 percent. There were no reported device failures.

This device has also been reported as use for BTT in the pediatric population, with two adolescents (12 and 14 years of age) being supported for 85 and 128 days before successful implantation.[65]

## Third-Generation, Centrifugal Continuous Flow Pumps

The potential hemolytic consequences of having rotor bearings in contact with blood in the second-generation devices led to the development of the most recent, or third-generation devices. These have been designed without any components in direct contact with the bloodstream, using hydrodynamic or magnetic levitation to suspend an internal rotor that provides centrifugal, continuous flow. Table 51-5 summarizes the clinical data available for the second-generation devices.

### VENTRASSIST LVAS

The VentrAssist (VentraCor Limited, Chatswood NSW, Australia) is a small implantable centrifugal pump designed for DT and BTT. It uses a hydrodynamic rotor suspension, which avoids areas of slow and turbulent blood flow. The absence of bearings reduces rotor wear, enhancing the device's durability. It uses large rare-earth magnets with small gaps and a harmonic drive system. Weighing 298 g, it is 6 cm in diameter and 6.5 cm in length. The externally worn battery and controller provide power and control; the battery holds sufficient charge for up to 8 h. The small size of the device will permit its use in smaller adults as well as in children. The short inflow cannula connects to the left ventricular apex and the outflow cannula is anastomosed to the ascending aorta. It has a low potential for thrombosis due to a reduction of stasis and therefore requires minimal anticoagulation. This device has been studied in several multinational clinical trials.

Several smaller clinical trials evaluated the feasibility of using the VentrAssist for both BTT and DT (Pilot Trial, 9 patients; Pivotal Trial, 44 patients; US Feasability Study for BTT, 7 patients) from 2003 to 2005.[66] Results from these smaller trials were encouraging with no device

**TABLE 51-5: Clinical Data from Third-generation Devices**

failures over a cumulative device time of 33 years and a median support time of 180 days. Among the 33 patients who underwent device implantation for BTT, 82 percent were alive at the 5-month trial endpoint with 40 percent having undergone heart transplantation and another 42 percent alive and awaiting transplantation.[66] Results for the 16 patients who received a device as DT were equally good; 1- and 2-year survivals were 80 and 60 percent.[67] Recently the international experience with the VentrAssist device implanted in over 400 patients has been published.[68] Among 412 patients who underwent device implantation, 81 percent reached the endpoint of transplantation (36 percent), continued support (44 percent) or myocardial recovery (1 percent) and the longest period of support was in a patient who was alive with greater than 4 years of continuous support.

The future of this device, however, is uncertain. In 2009, following the deaths of three patients due to damaged electrical leads, the company temporarily stopped all new implantations. Following this event, the company manufacturing the device declared bankruptcy, and was liquidated as clinical trials were underway.

FIGURE 51-14 DuraHeart LVAS. (From Terumo Corporation, with permission.)

## DURAHEART LVAS

The DuraHeart LVAS (Terumo Heart, Inc., Ann Arbor, MI) is an active magnetically levitated centrifugal pump. The impeller is levitated by three electromagnets, and rotation is achieved by magnetic coupling between the impeller and the motor. The pump weighs 540 g, displaces 196 mL, and can generate flows up to 8 L/min (Fig. 51-14) at 120 mmHg head pressure with no residual left ventricular function.[69] The heparin-bonded inflow and outflow cannulas and pump blood chamber comprise the blood contacting surfaces. Warfarin anticoagulation is recommended. The device is commercially approved in Europe and Japan. Clinical trial enrollment was closed in December 2011 for a Pivotal BTT FDA investigation.

The initial clinical experience with the DuraHeart was a European, multicenter trial of 33 patients who underwent device placement for BTT.[70] This group had no device mechanical failures over a cumulative support duration of 28.7 patient-years.[71] Forty-two percent of patients went on to receive a heart transplant at a mean of 185 days. For those that remained on support awaiting transplant, a 2-year survival was 57%. An updated experience reporting on 82 European patients who underwent implantation of the DuraHeart showed no pump replacements after 6 months over a cumulative support time of 78 years and a median duration of support of 261 days.[71] Survival at 6 months and 1 year were 85 and 79%, respectively. The longest duration of support, at the time of the publication, was more than 4.1 years.

## HEARTWARE HVAD

The Heartware HVAD (Heartware International, Framingham, MA) is a continuous flow, centrifugal pump that is small enough (4 × 2 cm, 50 mL displacement) to be implanted in the pericardial space yet is capable of generating flows up to 10 L/min (Fig. 51-15). The only moving part is the impeller that is suspended directly in the bloodstream within the pump itself using magnetic and hydrodynamic thrust bearings, thus eliminating any physical contact between the impeller and the pump. The inflow cannula is integrated into the device itself that is placed directly into the apex of the heart, and the distal end is anastomosed to

FIGURE 51-15 Heartware HVAD. (With permission from HeartWare International (for World Heart Corporation), Framingham Mass.)

the ascending aorta. Implantation can be achieved through median sternotomy or left thoracotomy with or without the use of CPB. Warfarin anticoagulation is required. This device has been studied for use as both BTT and DT in the United States and internationally.

This device was initially evaluated in an international multicenter clinical trial in Europe and Australia among 23 patients with implantation as BTT.[72,73] The mean duration of support was 167 days (range 13–425 days) and actuarial survival at 6 months and 1 year were 91 and 86 percent. By the 180-day endpoint 2 patients underwent transplantation, 19 patients had continued device support, and successful weaning and device explantation occurred in one patient in this trial. A case report noted complete resolution of heart failure symptoms up to 6 months after explant.[74] Three groups have also reported successful biventricular support with the DuraHeart as well, with up to 189 days of successful support.[75–77]

Long-term data from the clinical experience among 99 patients implanted in Europe were equally promising.[78] The mean duration of support was 251 days with support longer than 6 months in 26 patients and support longer than 1 year in 6 patients. Among this group of patients, 22 were successfully transplanted, 4 were weaned and underwent device explantation, and 61 remained on support with a longest continuous support time of 1108 days. The actuarial survival was 80 percent at 2 years.

In addition, this device recently has been examined in a multicenter clinical trial in the United States for use as BTT. The ADVANCE study enrolled 140 patients on the heart transplantation list at 30 centers across the United States and was designed as a noninferiority analysis comparing the Heartware HVAD to previously approved and commercially available devices. These patients were compared with 499 patients from the INTERMACS registry who underwent implantation of any available device during the same period. Survival of the study group was 92 percent at 180 days and 91 percent at 1 year, compared with 90 percent and 86 percent in the control group, thus establishing the Heartware HVAD as comparable to existing devices for BTT.[79]

The ENDURANCE trial is currently underway and has been designed to enroll 450 patients at 50 centers across the United States to examine the application of this device for DT in a randomized, controlled fashion among patients with advanced heart failure.

## EVAHEART LVAD

The EVAHEART LVAD (EVAHEART Medical, Pittsburgh, PA) is a centrifugal pump device with a unique thromboresistant coating over the surfaces of the pump housing, the impeller, and the cannula in order to reduce thrombotic and thromboembolic complications associated with device implantation. This device is implanted in the preperitoneal position and is capable of generating flows up to 14 L/min. Current clinical trials that began in 2010 are underway to evaluate this device for BTT applications.

**FIGURE 51-16** INCOR. (From Berlin Heart, Inc., with permission.)

Initial clinical trials in Japan among 14 patients who received EVAHEART devices as BTT demonstrated good results.[80] Over a cumulative device support time of 12.9 years there were no device failures and 6-month, 1-year, and 2-year survivals were 91, 78, and 78 percent, respectively. Support times of >1 year were reported in 43 percent, and over 2 years in 21 percent of patients. This device is currently being investigated in clinical trials in the United States.

## INCOR

The INCOR (Berlin Heart Inc., The Woodlands, TX) is a magnetically levitated, fully implantable axial flow pump. The impeller is capable of rotating at a speed of 12,000 rpm and can generate flows of 7 L/min at pressures up to 150 mm Hg (Fig. 51-16). The INCOR requires about 8.5 W of power, weighs 200 g, and is 30 mm in diameter. The pump is titanium-based with silicone conduits. Anticoagulation is with warfarn and aspirin. The battery and power pack weigh about 1.5 kg and can be carried on one's person, with a TETTS energy transfer system. This device is currently in clinical trials in the United States that began in 2009.

This device has been implanted in 212 patients for various indications in European clinical trials with good results.[81] No pump failures were reported and patients had a mean duration of support of 182 days. Eventual outcomes were transplantation in 31 percent, continued support in 20 percent and device explantation in 5 percent.

## LEVACOR

The Levacor LVAD (WorldHeart Corp., Salt Lake City, UT) is a continuous flow, centrifugal rotary pump with an impeller suspended by magnetic levitation. Despite a low profile (maximum dimensions of 38 mm) it is capable of generating flows up to 10 L/min (Fig. 51-17). Warfarin anticoagulation is required. It is implanted in a preperitoneal location with inflow cannula placed in the left ventricular apex and

FIGURE 51-17 Levacor. (With permission from HeartWare International (for World Heart Corporation), Framingham Mass.)

outflow cannula anastomosed to the ascending aorta. This has been an evolution from the Novacor and the prototype HeartSaver and is the latest device in this series. This device has been successfully implanted in an early feasibility study and is currently under investigation in a United States BTT clinical trial.[82]

## Total Artificial Heart

### SYNCARDIA (CARDIOWEST) TOTAL ARTIFICIAL HEART

The Syncardia (formerly called CardioWest) TAH (Syncardia Inc., Phoenix, AZ) was developed at the University of Utah by Robert Jarvik. Its precursor, the Jarvik 7, was implanted by DeVries in 1980.[7] This is a pneumatically driven biventricular pulsatile device, which is implanted orthotopically.[83] It consists of two ventricular chambers connected to the native atria and incorporates a 27-mm Medtronic-Hall mechanical tilting-disk valve (inflow). The blood-contacting surface consists of an air-compressed polyurethane sac (Fig. 51-18). The pneumatic hose and drive line exit transcutaneously to a console that controls the pump and delivers the compressed air. The pump delivers a stroke volume of 70 mL and is capable of achieving a maximum flow rate of 8 L/min. Warfarin anticoagulation is required. A strict size criterion is observed in selecting patients for this device (Table 51-6). Limitations of this device include the large, cumbersome console and frequent maintenance of the pneumatic inlets and outlets, although recently three patients have been successfully discharged to home with portable drivers. It is currently FDA approved for BTT.

Since its introduction, over 850 devices have been implanted internationally for BTT indications with a cumulative experience of greater than 190 patient-years.[84] The initial feasibility studies were conducted in a multicenter trial in the United States.[85] Inclusion criteria for this trial were: eligibility for transplantation, NYHA class IV heart failure, BSA 1.7 to 2.5 $m^2$ and hemodynamic insufficiency classified as either CI <2.0 L/min/$m^2$ or conventional cardioactive drugs at maximal dose with or without IABP or use of CPB. Exclusion criteria were any prior use of VAD, pulmonary hypertension with pulmonary vascular resistance >640 dyne·sec·$cm^2$, dialysis in previous week or serum creatinine >5 mg/dL, cirrhosis with bilirubin >5 mg/dL, or presence of cytotoxic antibodies. In this trial, 81 patients who received the Syncardia TAH were compared with 31 patients who met inclusion criteria but who did not receive any MCS. Rates of survival to transplantation were significantly

FIGURE 51-18 Syncardia TAH. (With permission from SynCardia Systems, Inc.)

**TABLE 51-6: CardioWest Total Artificial Heart: Criteria for Implantation**

| |
|---|
| Body surface area ≥1.7 $m^2$ |
| Cardiothoracic ratio >0.5 |
| Left ventricular diastolic dimension >66 mm |
| Anteroposterior distance (sternum to T10, by computed tomography) >10 cm |
| Combined ventricular volume (measured by computed tomography) >1500 mL |

improved in the Syncardia TAH group compared with the control group, 79 vs 46 percent, $p$ <0.001. One-year survival rates were also improved with the Syncardia TAH compared with the control group, 70 vs 30 percent, $p$ <0.001. Overall 1- and 5-year survival for patients who received the Syncardia TAH as BTT therapy was 86 and 64 percent, respectively. Among all patients, there was one device failure that resulted in a patient death.

A follow-up study by Leprince et al. reported a single institution experience of 127 patients implanted with the Syncardia TAH over a 15-year period.[86] There was one device failure in 3606 cumulative device support days. Rates of survival to transplantation increased over time with 43 percent before 1993, 55 percent between 1993 and 1997, and 74 percent reaching transplantation after 1997.

An analysis based upon the initial experience of 81 patients in the United States trial was recently published in an attempt to identify which patients might benefit from this device.[87] The authors of this study found that independent predictors of mortality were a history of smoking or coagulopathy with PT >16 s in the implant to posttransplant period. Interestingly these were different risk factors for mortality than previously reported for LVAD or separate biventricular support devices which are right heart failure, previous mediastinal operations, mechanical ventilation before implantation, and end organ dysfunction of the renal, hepatic, or pulmonary organ systems.

**FIGURE 51-19** Abiocor TAH. (With permission from ABIOMED, Inc.)

## ABIOCOR TOTAL ARTIFICIAL HEART

The AbioCor TAH (ABIOMED Inc., Denver, MA) is inserted orthotopically after excising the native ventricles. The energy converter is situated between the two ventricles and consists of a high-efficiency miniature centrifugal pump.[88] A two-position switching valve is used to alternate the direction of the hydraulic flow between the right and left pumping chambers, thus alternating systole between the two chambers. The stroke volume of each chamber is 70 mL (Fig. 51-19). Pumping rates can be adjusted between 75 and 150 bpm with a resultant flow rate of 4 to 8 L/min. All blood-contacting surfaces of the AbioCor TAH, including the trileaflet valves, are made of polyether urethane, resulting in a smooth, continuous blood-contacting surface. An atrial balance chamber permits adjustment of stroke volumes and maintains balance between right and left chambers. This unique feature obviates the need for a compliance chamber. The energy transfer is achieved by TETTS. The controller and the battery modules (Ni-Cad) are implanted preperitoneally. Externally worn components include the TETTS primary and Ni-Ion battery modules. Anticoagulation with warfarin is required. This device is available as a Humanatarian Device Exemption from the FDA and has been investigated in a clinical trial.

Initial data from clinical trials of the AbioCor TAH have been reported. Inclusion criteria were patient age of 18 years or more, ineligibility for cardiac transplantation, a high likelihood of dying within 30 days while on optimized medical management, an acceptable device-fitting evaluation, and biventricular failure with inability to be weaned from temporary MCS. Exclusion criteria were heart failure with significant potential for reversibility, patients on chronic dialysis, irreversible liver failure, blood dyscrasias, suspected or active systemic infection, a positive serum pregnancy test result, severe peripheral vascular disease, transient ischemic attack or stroke secondary to atherosclerosis, psychiatric illness (including drug or alcohol abuse), and lack of an adequate social support system. All patients had a 30-day predicted mortality of more than 70 percent based on the AbioScore prognostic model or acute myocardial infarction shock scores. The AbioScore mortality prediction model was developed based on previous prognostic models, including measurements that had the highest prognostic value for mortality in patients with end-stage heart failure. These factors include age, serum sodium, renal function, need for inotropic or intra-aortic balloon pump support, body-mass index, left ventricular end-diastolic diameter, peak exercise oxygen consumption, and New York Heart Association (NYHA) functional class. Eligible candidates were screened for device fitting using a proprietary software program (AbioFit, ABIOMED).[89] The primary end point of these first trials was the AbioCor's impact on all-cause mortality in patients with severe heart failure and a predicted life expectancy of less than 30 days despite optimized medical management. Secondary end points included a determination of adverse events, device malfunction, complications related to the device, and quality of life. Thusfar, 14 implants have been

performed in the United States, with most of the patients completing 60 days successfully.[88,89] The preliminary results revealed two intraoperative deaths (due to intraoperative bleeding or aprotinin reaction) and four late deaths (one from multisystem organ failure and three related to cerebrovascular accidents). Six patients recovered to the point of being able to take multiple trips outside of the hospital, with two patients reaching hospital discharge.[87] There has been one long-term survivor with this device, and no implantations have occurred since 2004.

### Penn State TAH

The Penn State TAH (ABIOMED Inc., Danvers, MA) was developed at Penn State University with funding from the National Heart, Lung, and Blood Institute (NHLBI), and later developed with a corporate partnership with Abiomed. It is a fully implantable, orthotopically placed biventricular electromechanical total replacement system. The pump consists of a rigid titanium casing enclosing polyurethane blood sacs and an energy converter. This device utilizes Delirin monostrut valves to provide unidirectional flow.[90] The energy converter is composed of a brushless DC electric motor, which actuates a roller screw with pusher plates. Mechanical compression of the blood sacs by the pusher plates against the rigid housing results in alternate emptying of the blood. It has low associated vibrations and minimal noise. It has a stroke volume of about 64 mL and can reach a maximum output of about 8 L/min. Physiologic sensing is through the end-diastolic volume estimated from the motor speed and voltage; this provides the balance between the left- and right-sided pump outputs (akin to the LionHeart). The energy source is comprised of TETTS and quick-charging Ni-Cad batteries. A compliance chamber is connected to the motor housing and implanted internally. This device has undergone preclinical testing, feasibility, and durability studies, but no clinical data in patients have been published.[90]

## NEWER DEVICES

There are several, newer-generation devices that are being developed for clinical use. The majority of these are in preclinical in vitro bench studies and in in vivo animal studies and have either not yet proceeded to clinical use or have little published data on their use in patients.

### HeartQuest VAD

The HeartQuest VAD (MedQuest Products Inc., Salt Lake City, UT) is an implantable, centrifugal pump housed in a titanium casing. It uses magnetic levitation to suspend and drive a self-centering impeller. The inflow cannula is placed in the left ventricular apex with the outflow cannula anastomosed to the ascending aorta. This device can provide 1.5 to 9 L/min of blood flow. It has a bench durability of 5 years, with low anticoagulation requirements.[91]

**FIGURE 51-20** HeartMate III. (Reprinted with the permission of Thoratec Corporation.)

### HeartMate III

The HeartMate III (Thoratec Corp., Pleasanton, CA) is a fully implantable, magnetically suspended centrifugal pump. It incorporates the textured blood surface used in previous Thoratec devices. It measures 6.9 cm by 3.5 cm, has a displacement volume of 195 mL, and weighs 500 g (Fig. 51-20). This device produces a mean blood flow of 4.3 L/min (±1.5 L/min) and is powered by TETS[69] Bench studies have shown up to 40 months of continuous use without device failure.[92]

### TandemHeart pVAD

The TandemHeart pVAD (CardiacAssist Technologies, Inc., Pittsburgh, PA) is a centrifugal pump that can be rapidly deployed by cardiologists in the cardiac catheterization laboratory by femoral arterial access. It is light in weight (280 g) and requires only 7 mL of priming fluid to accommodate

**FIGURE 51-21** TandemHeart. (From CardiacAssist, Inc, with permission.)

both small and large patients (Fig. 51-21). It is intended for reversible causes of cardiac failure following percutaneous revascularization.[91] The pump is powered by a stationary electromagnetic motor, which drives a rotor and impeller. Rotating at 2700 to 4700 rpm, it is capable of generating flows up to 6 L/min and pressures up to 90 mm Hg. Heparin anticoagulation is required during support.

Burkhoff et al. randomized 42 medical patients with cardiogenic shock to receive the TandemHeart pVAD or conventional IABP therapy.[93] Although the TandemHeart pVAD was associated with significant improvements in cardiac index, MAP, and PCWP, there were no differences in 30-day survival or adverse outcomes between the groups.

Recently, this device has been investigated for use in postcardiotomy shock in a BTR fashion.[94] Initial feasibility studies were completed in 11 patients with a mean duration of support of 88 h. Nearly three-quarters of all patients could be weaned from the device and 55 percent survived to discharge. Survival at 1 and 4 years were 46 and 36 percent, respectively.

## AB-180 iVAD

The AB-180 iVAD (CardiacAssist Technologies, Inc., Pittsburgh, PA) is a surgically implantable version of the TandemHeart pVAD (described above). A 10-mm polytetrafluoroethylene (PTFE) graft conducts outflow to the aorta. A percutaneous cable connects to an integrated infusion pump delivering lubrication and anticoagulation fluid, a flow estimator, and a power line to the VAD. This device can be deployed for postcardiotomy syndrome, acute myocarditis, and acute postinfarction myocardial failure and shock.[95,96]

## Kriton VAD

The Kriton VAD (Kriton Medical, Miramar, FL) is a small centrifugal pulsatile device that is fully implantable. The impeller of the pump is supported by a passive radial magnetic bearing that acts in synergy with hydrodynamic bearings. Torque is transmitted to the impeller by electromagnetic coupling via an integrated axial flux gap motor. It can displace 48 mL and generate an output up to 15 L/min. Weighing only 195 g with an extracardiac volume of 28 mL, this device is intended for long-term use and has undergone extensive preclinical testing.[97]

## CorAide LVAS

Developed at the Cleveland Clinics, the CorAide LVAS (Arrow Int., Reading, PA) is a small continuous-flow centrifugal pump. It has a magnetically suspended rotor, weighs 293 g, and capable of generating blood flows up to 6 L/min. It replaced the LionHeart LVAS in 2005. In preclinical trials, it has shown promise without requiring anticoagulation.[98] Thusfar it has been implanted in European trials in five patients with successful outcomes out to 6 months having been reported.[99]

## Kantrowitz CardioVad

The Kantrowitz CardioVad (LVAD Technologies Inc., Detroit, MI) has three main parts: a blood pump that is implanted on the lateral aspect of the descending thoracic aorta, a connector for an external power source, and a drive unit to power the pump. The pump, an inflatable avalvular polyurethane bladder, is sutured in place after excising a lateral portion of the aorta. It is about 6.5 cm in length and capable of displacing 60 mL of blood when inflated. The blood-contacting surface is textured so that pseudointima may form on it.[100] No anticoagulation is needed and an external air pump mounted in the external drive unit inflates and deflates the blood pump synchronously but out of the phase with heart contractions. The diastolic augmentation reduces left ventricular afterload, increases cardiac output, and improves coronary perfusion.

Initial feasibility studies among the first five patients showed that this device significantly increased cardiac index by 36 percent and decreased heart failure symptoms (NYHA IV to II) while improving renal function.[100] An updated clinical experience with this device among 9 patients had a range of duration of support from 2 to 458 days with a total support time of 1082 days, 557 of which were spent out of the hospital.[101]

## Pittsburgh Streamliner Mixed Flow Pump

The Streamliner, the first magnetic-bearing LVAD, is named for the way it provides minimal disturbance to blood flow. Developed at the McGowan Center for Artificial Organ Development, a subdivision of the Department of Surgery at the University of Pittsburgh School of Medicine, the

FIGURE 51-22 EXCOR. (From Berlin Heart, with permission.)

Streamliner operates at approximately 7500 rpm, supplementing the action of a weak or damaged heart.[96]

## Excor

The EXCOR (Berlin Heart Inc., The Woodlands, TX) is a pneumatically actuated paracorporeal pump that can support both ventricles (Fig. 51-22). The EXCOR stroke volume ranges from 10 to 80 mL, permitting its use in adults and children. It is available with two alternative types of valve systems: a mechanical tilting disk and a polyurethane velum valve. The cannulas are made of silicone and are designed to reduce the incidence of thromboembolism and entry/exit site infections. There are two systems available for pneumatic support. One is a stationary drive and the other is a mobile unit. The stationary unit (called Ikus) is capable of supporting both ventricles and can run in synchronous and asynchronous modes; each ventricle can be operated independently. The mobile unit (called Excor) weighs 8.7 kg with two power packs and features a physiologically adaptive synchronous operation. Preliminary studies in children have shown this device to be useful as BTT and BTR therapy in this patient population.[102,103]

## Abiomed Impella

The Abiomed Impella (Abiomed Inc., Danvers, MA) is a catheter-based device that is inserted into the aorta, across the aortic valve into the left ventricle (Fig. 51-23). The Impella LP 2.5 is designed for placement through femoral arterial access by interventional cardiologists in the angiography suite, and

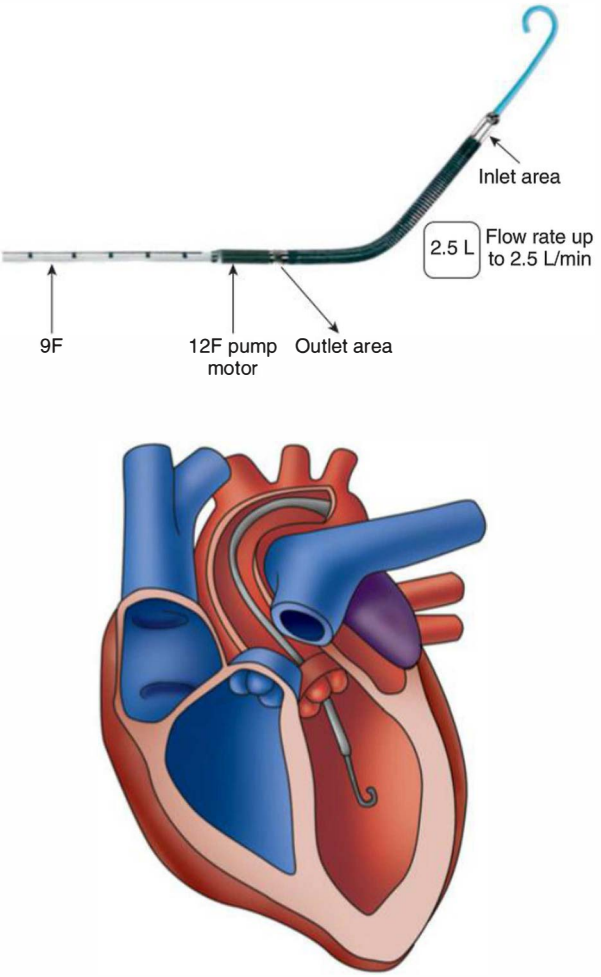

FIGURE 51-23 Abiomed-Impella. (From ABIOMED, Inc., with permission.)

the LP 5.0 by cardiac surgeons through either aortotomy or the femoral/axillary artery. Current indications include high-risk percutaneous coronary interventions, postcardiotomy heart failure, and cardiogenic shock following acute myocardial infarction. Preliminary data demonstrated an improvement in survival compared to IABP for patients with postcardiotomy heart failure.[104]

## Levitronix Centrimag

The Levitronix Centrimag (Levitronix Inc, Waltham, MA) is a short-term, extracorporeal device that provides continuous flow via a centrifugal pump (Fig. 51-24). It is capable of delivering flows up to 9.9 L/min and has a contact-free magnetically-levitated impeller without mechanical bearings or seals (Fig. 51-23).

**FIGURE 51-24** LevitronixCentrimag. (Levitronix Corp., with permission.)

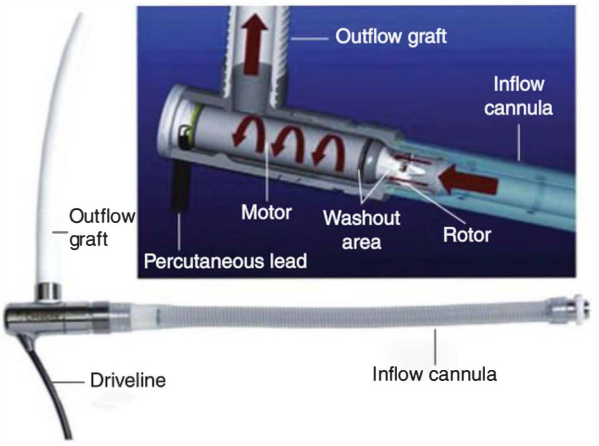

**FIGURE 51-25** Circulite LVAS. [Reproduced with permission from Meyns BP, Simon A, Klotz S, et al. Clinical benefits of partial circulatory support in New York Heart Association class IIIb and early class IV patients. *Eur J Cardiothorac Surg.* (Epub ahead of print.)]

This device is currently under clinical investigation in an ongoing trial, the Centrimag Pivotal Trial, led by the Thoratec Corporation. Preliminary data in 12 patients with cardiogenic shock following acute myocardial infarction that was refractory to maximal medical management demonstrated a successful bridge to definitive procedure (coronary revascularization, long-term VAD placement) or recovery with 56 percent of patients discharged from the hospital and a 1-month survival of 67 percent.[105]

## Circulite

The Circulite (Circulite, Saddle Brook, NJ) is the smallest implantable device for long-term support and is the size of a AA battery (Fig. 51-25). This device was specifically designed to provide partial support to patients with class IIIb and early class IV NHYA heart failure, and is capable of flows up to 3 L/min. This device has an inflow cannula placed into the left atrium and an outflow graft placed into the right subclavian artery that are implanted without CPB through a mini-thoracotomy incision. Current prototypes in development will feature completely percutaneous placement of the inflow cannula via a transseptal system and outflow cannula to the subclavian artery via an anastomotic connector.

This device has been examined in a clinical trial conducted in Europe.[106,107] Among 35 patients in this group, the mean support time was 5 months with the longest greater than 14 months and survival was 91 percent to either hospital discharge or transplantation. Of these patients, 14 were successfully bridged to transplantation at a median time of 3.5 months. Physiologic parameters, including cardiac index, mean arterial pressure, and PCWP were all increased, and pulmonary artery pressures were decreased following device implantation. A trial in the United States is planned for 2011.

## Other Devices

Other devices in development, preclinical, and in some cases early clinical testing are the MiTi Heart VAD (MiTi Heart Corporation), MagScrew for VAD and TAH (Foster Miller Technologies), and an external cardiac support device called ParaCor (Paracor Surgical Inc.). Other heart failure support devices that alter the geometry of the left ventricle are the CorCap Cardiac Support Device (Acorn Cardiovascular Inc.) and the Myosplint System (Myocor Inc., Maple Grove, MN).[108,109]

# PATIENT SELECTION

Currently, MCS can be considered for BTR, BTT, and DT. Consideration is based on the indication for support and the operative risk involved for the patient. Profound heart failure due to chronic congestive heart failure or acute postcardiotomy pump failure are the most common indications for the institution of MCS. Candidates for support typically display clinical indices of chronic heart failure, with PCWPs in excess of 20 mm Hg, cardiac indices less than 2.0 L/min/m$^2$, and systolic blood pressures less than 80 mm Hg despite inotropic support.

For BTR indications, including postcardiotomy failure, short-term support with a centrifugal pump or a pulsatile

paracorporeal device is appropriate, since these devices are relatively easy to implant and maintain. If necessary, these devices can be exchanged for longer term pulsatile or axial flow devices. The option of implanting a TAH for DT is still impeded by the limited experience with these devices, but as experience grows, TAH and the smaller axial flow devices with portable consoles may be suitable devices for these patients.

## PREOPERATIVE RISK FACTORS FOR VAD THERAPY

One of the first studies to identify risk factors predictive of postoperative outcomes in VAD patients used a weighted assessment of 24 individual variables in a series of 26 patients.[110] Different types of devices were used, with 70 percent of the subjects receiving biventricular support. The risk factors most strongly associated with adverse outcomes included age greater than 50 years, preoperative cardiopulmonary resuscitation, mechanical ventilation or $FIO_2$ greater than 70 percent, ECMO, and blood urea nitrogen greater than 60 or a serum creatinine greater than 2.2 mg/dL.[110] Similarly, a review of 56 patients from the Cleveland Clinics and Columbia Presbyterian Hospital between 1990 and 1994 identified oliguria, central venous pressure greater than 16, mechanical ventilation, coagulopathy, and repeat sternotomy as risk factors.[111,112] Survival associated with VAD implantation also correlated well with APACHE II scores, which were significantly improved in patients supported by LVADs. Survival times determined by Kaplan–Meier analysis and Cox proportional analysis after adjustment for APACHE II scores were better for MCS ($p$ <0.02).[113]

A multivariate analysis of 464 VAD patients obtained from the Novacor European Registry revealed that independent risk factors for death after device implantation included respiratory failure associated with septicemia, right heart failure, age greater than 65 years, acute postcardiotomy failure, and acute myocardial infarction. In the absence of any risk factors, the 1-year survival rate was 60 percent, including posttransplant survival. Any risk factors reduced survival rates to 24 percent.[114] In a prospective multicenter clinical trial conducted at 24 centers in the United States with 280 transplant candidates treated with the HeartMate XVE LVAD, increasing age, prior heart surgery, and hepatic/renal dysfunction were the major predictors of adverse outcomes following device implantation.[39] In a retrospective analysis of 97 LVAD patients, including 64 pneumatic devices and 36 electric devices, significant risk factors for death included a preoperative need for ventilator support or ECMO, elevated blood urea nitrogen, elevated serum creatinine, hyperbilirubinemia, and low pulmonary artery pressures. Postoperative risk factors included reoperation for bleeding, RVAD support requirement, dialysis, and device failure.[115]

**TABLE 51-7: Columbia University and Cleveland Clinics Scoring System for Predicting Mortality after LVAD Implantation**

| Variable | Score |
|---|---|
| Revised system | |
| Ventilation | 4 |
| Redo surgery | 2 |
| Previous LVAD insertion | 2 |
| Central venous pressure >16 mm Hg | 1 |
| Prothrombin time >16 s | 1 |
| Original system | |
| Urine output <30 mL/h | 3 |
| Ventilation | 2 |
| Central venous pressure >16 mm Hg | 2 |
| Prothrombin time >16 s | 2 |
| Redo surgery | 1 |

In 1995, Columbia University and the Cleveland Clinics proposed a scoring system to predict successful outcomes after LVAD implantation; it was further expanded with evolving technology (Table 51-7).[111,116] The scoring system is based upon 130 patients who received the vented electrical HeartMate device from 1996 to 2001 (Table 51-8). A score higher than 5 corresponds with a 47 percent mortality, compared with a 9 percent mortality for a score less than 5 (79 percent positive predictive value vs 70 percent negative predictive value).[116]

## CARDIAC CONSIDERATIONS

### Valvular Heart Disease

Valvular stenosis and regurgitation often have significant implications for assist device function. Mitral stenosis can lead to impaired LVAD filling and flow rates. A competent aortic valve is necessary for proper LVAD function; severe aortic regurgitation should be corrected with device implantation. Mild-to-moderate aortic regurgitation can worsen once left ventricular support is initiated because of a reduction in left ventricular pressure and an increase in aortic root pressure. VADs do not completely unload the left ventricle, leading to some flow across the aortic valve. This low, intermittent flow is inadequate to wash an existing mechanical aortic prosthesis. Many feel that mechanical valves should be replaced by bioprosthetic valves at LVAD implant to prevent thrombus formation and subsequent embolism.

### Right Ventricular Function

When significant right ventricular dysfunction exists, biventricular support should be considered. If right ventricular failure is not recognized prior to the implantation of left ventricular support, unique problems can arise that may

**TABLE 51-8: Factors Important in Selecting a Mechanical Assist Device**

| Factor | Device |
|---|---|
| Duration of support | |
| Short term | Centrifugal pumps |
| | Paracorporeal devices (e.g., Thoratec VAD, ABIOMED BVS 5000) |
| Short- to medium term | Ventricular assist devices (Novacor, HeartMate, LionHeart) |
| Long term | Ventricular assist devices (e.g., Novacor, HeartMate, LionHeart) |
| | Total artificial heart (e.g., AbioCor TAH, CardioWest TAH) |
| Aim of support | |
| Bridge to transplant | Centrifugal pumps |
| | Paracorporeal devices (e.g., Thoratec VAD, ABIOMED BVS 5000) |
| | Ventricular assist devices (e.g., Novacor, HeartMate, LionHeart) |
| Bridge to recovery | Ventricular assist devices (e.g., Novacor, HeartMate, LionHeart) |
| | Axial flow pumps (e.g., DeBakey, HeartMate II, Jarvik 2000) |
| Destination therapy | Ventricular assist devices (e.g., Novacor, HeartMate, LionHeart) |
| | Axial flow pumps (e.g., DeBakey, HeartMate II, Jarvik 2000) |
| | Total Artificial Heart (e.g., AbioCor, CardioWest) |
| Type of support | |
| Univentricular | All devices |
| Biventricular | Paracorporeal devices (Thoratec VAD, ABIOMED BVS 5000) |
| | Total Artificial Heart (e.g., AbioCor, CardioWest) |
| Technical factors | |
| Small body size | Axial flow devices (e.g., DeBakey, Jarvik 2000, HeartMate II) |
| Size of device | |
| Anticoagulation | Extracorporeal pumps |

necessitate a device change and possibly lead to significant morbidity and mortality.[117] Unfortunately, current biventricular support devices are cumbersome, with large consoles limiting patient mobility. Preoperative risk factors for right ventricular failure after LVAD insertion include hyperbilirubinemia, elevated creatinine, and mechanical ventilatory support.[118] Ochiai and colleagues found that several factors had an 80 percent predictive value in determining the need for right ventricular assistance: right ventricular end-diastolic dimension of 8.5 cm, right ventricular end-diastolic volume of 200 mL, a mean pulmonary artery pressure of 60 mm Hg, and a mean right atrial pressure of 70 mm Hg.[119]

## Atrial and Ventricular Arrhythmias

Atrial fibrillation and atrial flutter can lead to inadequate right ventricular filling and thrombus formation. Both cardioversion and anticoagulation are essential, even if the device does not otherwise require anticoagulation. Ventricular arrhythmias can be considered as a relative contraindication for mechanical support, although it has been shown that device flow can be maintained adequately during ventricular fibrillation in the setting of low pulmonary vascular resistance. In conclusion, arrhythmias should be treated prior to VAD implantation.

## Intracardiac Shunts

Because of the significant right-to-left shunting that can result after unloading the left ventricle, it is important to close any patent foramen ovale or atrial septal defects at the time of assist device implantation.

# OTHER CONSIDERATIONS

Noncardiac organ function plays an important role in clinical outcomes with mechanical device support. Also important is the timing of device insertion, but this is largely influenced by the referral pattern, institutional preferences, and surgeon-specific factors. Some poor outcomes following device therapy are due to delay in instituting device implantation. Ideally, device implantation should be considered prior to the onset of organ failure.

## Pulmonary Function

Although there are no consensus criteria for pulmonary function testing prior to assist device implantation, a $FEV_1$ greater than 50 percent predicted, FVC of 50 percent predicted, and $DL_{CO}$ of 50 percent predicted are usually baseline requirements in selecting candidates for mechanical support. Although LVAD therapy has been shown to reduce pulmonary vascular resistance, this is not always observed. When pulmonary vascular resistance is fixed, unloading of the left ventricle by the device does not lead to a significant reduction of right ventricular afterload and increased pulmonary blood flow. In patients with severe pulmonary disease, preoperative computed tomography of the chest is warranted.

## Renal Function

Many studies have identified renal dysfunction as a significant predictor of poor outcomes following assist device implantation. A thorough preoperative evaluation of renal dysfunction is important to determine reversibility. A candidate's baseline renal function prior to the onset of cardiac failure or cardiogenic shock and the potential for recovery should be considered. Many centers now employ aggressive renal support via hemodialysis and hemofiltrationwhich, to

some extent, has made many patients suitable for mechanical device therapy who would otherwise have been denied. An elevated creatinine has been shown to be a negative risk factor for LVAD insertion.[120] Similarly, elevated blood urea nitrogen greater than 40 mg/dL has been shown to be a risk factor for BTT survival. Severe right ventricular dysfunction and volume overload with a right atrial pressure above 20 mm Hg can lead to changes in glomerular filtration, with a resultant decrease in urine output and resistance to diuretic therapy.

### Hepatic Function

Significant hepatic dysfunction or failure can be detrimental in assist device patients. Prolongation of the international normalized ratio (INR) is one of the most significant risk factors for complications in mechanical assist patients, associated with significant perioperative bleeding and transfusion requirements, worsening coagulopathy, right ventricular dysfunction, and multiorgan-system failure.[121] A total bilirubin greater than 3.6 mg/dL or a direct bilirubin greater than 1.2 mg/dL (e.g., cardiac congestion, drug toxicity, hepatitis, alcohol abuse) is an independent risk factor for adverse outcomes.[122] If these markers are found to be elevated in a candidate's evaluation, a thorough investigation to assess the degree and severity of hepatic dysfunction is warranted. Patients with right heart failure with resultant hepatic congestion may need right ventricular support in addition to left ventricular support. These and other considerations are particularly important when DT is being considered.

### CNS Function

The potential for postoperative long-term rehabilitation after device insertion is based on an understanding of the workings of the device, consoles, various alarms, and device maintenance. Hence a major irreversible neurologic deficit or cognitive impairment, which would render patients incapable of managing their devices, is generally a contraindication for device implantation. However, limited motor deficits are not singular contraindications to mechanical device support; in such cases, determinations should be made in consultation with neurologists and support staff.

## DEVICE SELECTION

The selection of a mechanical support device is largely dependent on the candidate's clinical situation. Selection is first and foremost dependent on the duration of support needed (e.g., short-, medium-, or long term); the aim of support (i.e., BTT, BTR, or DT); whether univentricular or biventricular support is needed; patient size (many devices are limited to a BSA >1.5 $m^2$); and the size of the device itself, particularly when pediatric support is being considered. Anticoagulation requirements and the degree of support represent important secondary issues. Long-term durability and mechanical robustness are important factors when DT is considered. How some of the factors determine device selection is outlined in Table 51-8. A decision-making flowchart for device selection is offered in Figure 51-26.

## SURGICAL MANAGEMENT

### Preoperative Preparation

As outlined earlier, every attempt should be made to optimize distal organ function. Common interventions include IABP, diuresis, pulmonary vasodilators (e.g., prostaglandin $E_1$), hemodialysis/hemofiltration, and the replacement of coagulation factors. A right atrial pressure below 12 mm Hg, PCWP less than 20 mm Hg, and cardiac index greater than 2.0 are target indices prior to insertion of the device. Pre- or intraoperative echocardiographic studies can help identify a patent foramen ovale or small atrial septal defect and assess valvular and ventricular function.

### Operative Technique

Most VADs are implanted through a median sternotomy on CPB (Fig. 51-27).[123] The devices can be placed within intra- or preperitoneal pockets. A preperitoneal pump pocket is created by extending the median sternotomy incision. The size of the device affects its location in many patients. Early attempts at placing the device intraperitoneally resulted in colonic perforations, intestinal obstruction, and diaphragmatic hernias; this has led most surgeons to place these devices extraperitoneally. Care is taken to achieve meticulous hemostasis during pocket construction, since hemorrhage and the formation of pocket hematomas are among the most common complications. After the pocket is created, the device is primed and the driveline tunneled from the pocket to exit the right upper abdominal quadrant. The patient is then heparinized and the heart cannulated for CPB. An off-pump end-to-side anastomosis between the aorta and the outflow conduit can be performed in some patients using a partially occluding clamp. Left ventricular apical inflow cannulation is typically performed on CPB, creating a circular apical ventriculotomy, placing circumferential mattress sutures to anchor an apical connector, and connecting the LVAD inflow cannula to this connector. Some surgeons feel that apical inflow cannulation should be performed first to permit more accurate sizing of the outflow graft. Once the inflow and outflow connections have been made, the LVAD chamber is passively filled, followed by pump de-airing maneuvers. CPB is then weaned concomitantly with initiation of VAD function.

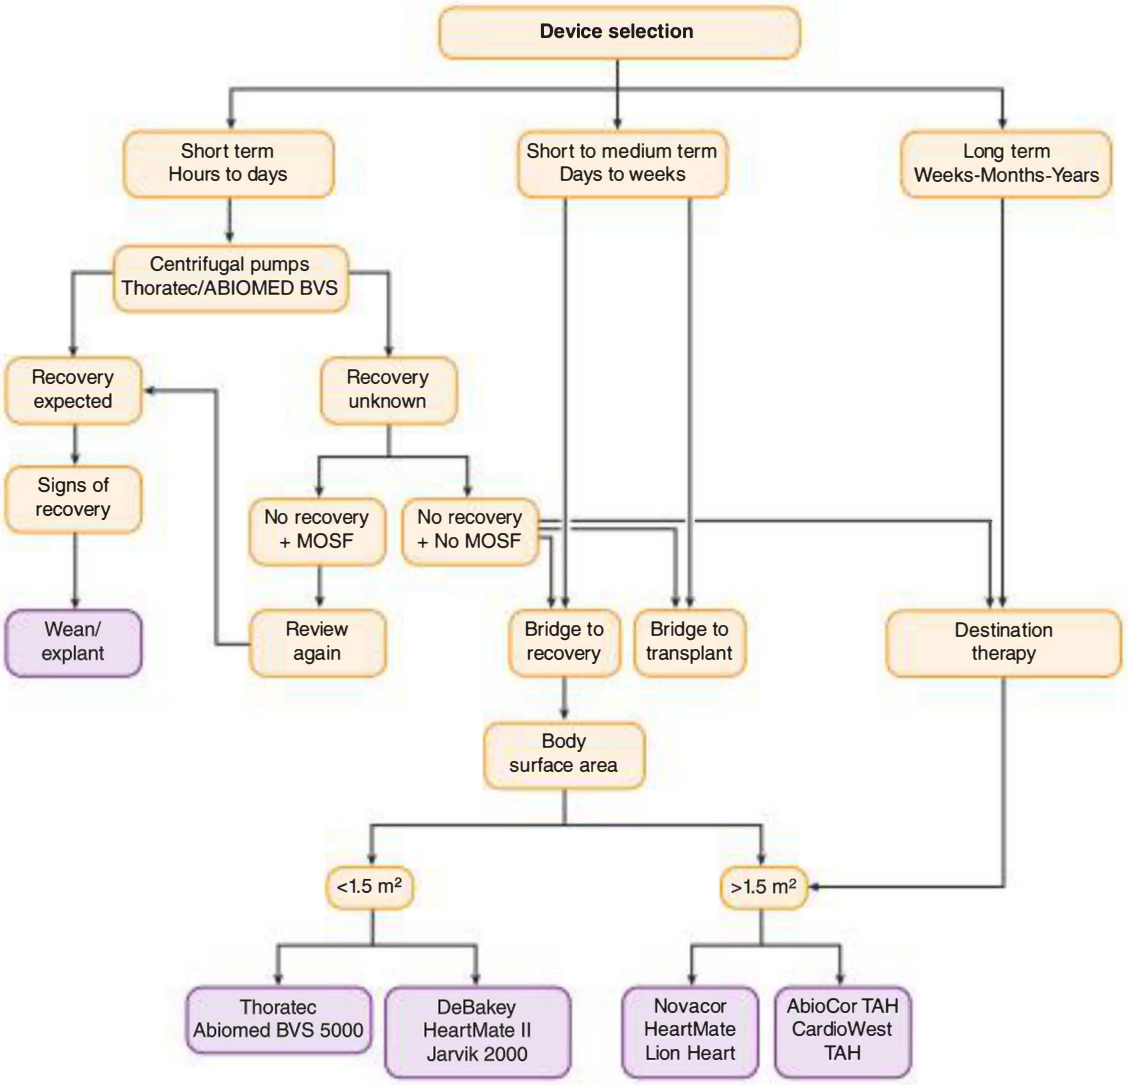

**FIGURE 51-26** Decision-making flowchart: device selection.

In addition, VAD implantation may be performed via median sternotomy without CPB. Off-pump VAD implantation at some centers has been associated with decreased operative times, ventilator time, inotropic support, and hospital stay compared to traditional on-pump VAD implantation.[124]

Several alternative methods exist for VAD implantation with different operative exposures, including subcostal and left thoracotomy approaches. These techniques are useful among patients who have had prior sternotomies and/or patent coronary bypass grafts that may be injured during median sternotomy, who need device exchange, or who otherwise may not tolerate the dissection needed for the traditional median sternotomy. These approaches may all be performed without CPB, but for each of these techniques, appropriate vascular exposure in the groin or chest should be obtained in case the need for emergent CPB arises. Subcostal approaches have been described with and without CPB for initial implantation or device exchange with good results (Fig. 51-28).[125–127] Device implantation through a left thoracotomy has also been employed, both on- and off-pump, with similar success (Fig. 51-29).[128–131]

## Postoperative Care

After LVAD implantation, early postoperative care focuses on optimizing and monitoring native right ventricular function in addition to the usual ICU procedures following cardiac surgery. Adequate right heart function can be fostered with pulmonary vasodilators (e.g., milrinone, nitric oxide).

Patients can be weaned to extubation once hemodynamics have been stabilized and hemostasis has been assured. Following this, early patient mobilization and nutritional repletion are undertaken. Heparin is typically used early postoperatively with long term anticoagulation regimens usually consisting of aspirin and warfarin.

### VAD Explantation

In BTT patients, VAD explantation at the time of transplantation can be complicated by dense adhesions around the device conduits. This situation can be somewhat ameliorated by wrapping the conduits with Gore-Tex. Regardless, upon reentry through the sternum, care must be taken to avoid damage to underlying cardiac and device structures.

## COMPLICATIONS

### Bleeding

Hemorrhage is the most common complication after assist device implantation.[26,132] Technical factors that can lead to increased bleeding include the creation of large pockets for device placement, loose device connectors and conduits, and insufficient hemostasis (e.g., cannulation sites, sternal edges). Bleeding can be caused by coagulopathy due to liver failure, prior antiplatelet and antithrombotic medications, and CPB-related platelet consumption.[112] Consequently, meticulous hemostasis, a low threshold for re-exploration, and judicious use of blood products and clotting factors are mandatory in device implantation. Nevertheless, once medical causes for hemorrhage have been corrected (hypothermia, thrombocytopenia, coagulopathy), if significant bleeding (>200 $cm^3$/h from chest tubes) or tamponade physiology develop, return to the OR for reassessment is indicated.

The incidence of significant bleeding was reported to be as high as 50 percent in early series, with up to 60 percent of patients undergoing re-exploration for hemorrhage.[26,132–134] With newer-generation devices in the most recent two clinical trials, postoperative transfusion of any blood products occurred in 76 to 81 percent, significant transfusion (>2 units) occurred in 53 percent, and reoperation for bleeding occurred in 30 to 31 percent.[58,60] Delayed sternal closure has been advocated by some in cases of severe coagulopathy or right heart dysfunction, with closure 24 to 48 h after device implantation to allow for achievement of hemostasis and recovery of right heart function prior to closure of the median sternotomy.[135]

### Infection

The reported incidence of device-related infections varies, but remains one of the most frequent complications after bleeding.[26] Among the first-generation devices, infection rates ranged from 49 to 66 percent and rates of significant sepsis were reported up to 41 percent.[26,136] The lack of standardized definitions and criteria for device-related infections have rendered reported infection rates rather inexact.[137] Rates of infection with the newer devices are significantly improved; however, this continues to be a source of morbidity and mortality. The third annual report of the Mechanical Circulatory Support Device Database of the International Society for Heart and Lung Transplantation reports an overall infection incidence of 32.5 percent with a 7.9 percent mortality rate.[138] Among clinical trials of newer devices, rates of localized infection (not device related) range from 28 to 49 percent, percutaneous lead infection of 14 percent, LVAD infection of 35 percent, and sepsis from 20 to 36 percent.[58,60] The risk of infection has been shown to be related to device and operator experience among retrospective reviews.[139,140]

### Thromboembolism

Thrombosis is associated with all devices, and can lead to device failure or distal thromboembolism. Historically, device implantation was associated with a thromboembolism incidence of 10 to 25 percent among early devices.[141] Better conduits that promote neointimal growth have reduced thromboembolic complications; nevertheless even the newer-generation devices, including axial flow and TAH devices, also suffer from thromboembolic complications. Among current devices, device thrombosis has been low at 2 to 4 percent, with distal thromboembolic events (mainly stroke) occurring in 7 to 8 percent of patients.[58,60]

### Multisystem Organ Failure

Multisystem organ failure after VAD implantation often results from preexisting unrecognized organ dysfunction. On the other hand, infection leading to sepsis, excessive hemorrhage, blood product transfusions, and prolonged ventilation can also contribute to postoperative multisystem organ failure. The incidence of postimplantation organ failure is reported to be between 10 and 30 percent. Careful preoperative assessment and proper timing for device insertion should serve to reduce this incidence.

### Right Ventricular Failure

Approximately 7 to 39 percent of patients experience some degree of right ventricular failure at the time of LVAD implantation.[142] Mechanisms for this phenomenon have been proposed. concomitant underlying right ventricular dysfunction may exist and may be unmasked at the time of LVAD implantation. Even nondysfunctional right ventricles are more sensitive to acute and significant changes in afterload with left ventricular device implantation. An increase in

**Predictors of right ventricular failure on multivariable analysis**

| Study | Definiton of RVF | Patients with RVF, *n* (% of sample) | Preoperative variables analyzed | Multivariable predictors |
|---|---|---|---|---|
| Ochiai et al. [8] | RVAD | 23 (9) | Demographics, echo, laboratory values, cardiopulmonary hemodynamics | Preop. MCS, female gender, nonischemic cardiomyopathy |
| Dang et al. [5] | RVAD, ≥14 d of inotropes, vasodilators, or both | 42 (39) | Patient demographics, pre- and intraop. cardiopulmonary hemodynamics | Intraop. RA pressure |
| Matthews et al. [9•] | RVAD, ≥14 d of inotropes or discharge on an inotrope, ≥48 h of inhaled NO | 68 (35) | Demographics, echo, laboratory values, cardiopulmonary hemodynamics, vasoactive medications | Preop. vasopressor requirement, Cr ≥2.3 mg/dL, AST ≥80IU/L, bilirubin ≥2.0 mg/dL |
| Fitzpatrick et al. [24•] | RVAD | 99 (37) | Demographics, echo, laboratory values, cardiopulmonary hemodynamics | Cardiac index ≥2.2 L/min/m$^2$, RVSWi 0.25 mm Hg/m$^2$/beat, prior sternotomy, SBP ≤96 mm Hg, severe RV dysfunction on echo, Cr ≥1.9 mg/dL |
| Drakos et al. [19•] | RVAD, ≥14 d of inotropes or discharge on an inotrope, ≥48 h of inhaled NO | 77 (44) | Demographics, echo, laboratory values, cardiopulmonary hemodynamics, vasoactive medications | Destination therapy, IABP, PVR quartile, inotrope dependence, BMI ≥30, ACE inhibitor/ARB use, β-blocker use |

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; AST, aspartate amniotransferase; BMI, body mass index; Cr, creatinine; echo, echocardiogram; IABP, intr-aortic balloon pump; MCS, mechanical circulatory support; NO, nitric oxide; PVR, pulmonary vascular resistance; RA, right atrial; RV, right ventricular; RVAD, RV assist device; RVF, RV failure; RVSWi, RV stroke work index; SBP, systolic blood pressure.

**FIGURE 51-30** Risk factors for development of right ventricular failure after device implantation. (Reproduced with permission from Romano MA, Cowger J, Aaronson KD, et al. cardiac output leads to increased venous return to the right heart, and transfusion and other vasoactive agents can lead to pulmonary vasoconstriction, leading to right heart failure. Early right ventricular failure after LVAD implantation can lead to poor filling of the LVAD, low pump outputs, and systemic hypoperfusion. Significant primary right ventricular failure has been defined as a right atrial pressure greater than 20 mm Hg on maximal drug support or a right atrial pressure greater than the PCWP. Occasionally, severe right ventricular failure necessitates placement of an RVAD to sustain LVAD output. Patients who develop right ventricular failure following device implantation have higher morbidity (increased ICU stay, renal failure, coagulopathy) and short- and long-term mortality rates (up to 38–43 percent) compared to those who do not.[142]

Multiple studies have identified various preoperative risk factors and devised risk stratification profiles for right ventricular failure following LVAD placement.[142] Clinical factors include older age, female sex, lower body surface area, redo sternotomy, postcardiotomy heart failure, nonischemic cardiomyopathy, and implantation for DT as risk factors for the development of right ventricular failure after device implantation. Other factors include preoperative evidence of right ventricular dysfunction (high RA pressures with or without pulmonary systolic hypertension, low right ventricular stroke work index, echocardiographic findings, hepatic congestion), cardiogenic shock with inotropic or intraaortic balloon pump support, and multisystem organ failure. The use of newer continuous flow devices may be related to a reduced risk of right heart failure.[143] A summary of risk factors identified by several groups on multivariate analysis and their related risk stratification profiles are outlined in Figure 51-30; individual risk scores may be calculated using any of these methods.

## OUTCOMES

### Bridge to Recovery

Not all patients with cardiogenic shock will require long-term device therapy or cardiac transplantation. For these patients, MCS can be used as a bridge until myocardial recovery can occur. The pathophysiology of cardiac remodeling following injury to the heart includes myocardial fibrosis, hypertrophy, and impaired myocyte contractility in the setting of abnormalities in neurohormonal signaling pathways. Data available from patients who have undergone device placement

**Suggested criteria for LVAD explantation**

| Authors | Suggested weaning criteria | Pump flow |
|---|---|---|
| Mancini et al. (1998)[18] | Peak $VO_2$ 20 mL/kg/min, peak CO >10 L/min | 1.6 L/min |
| Khan et al. (2003)[12] | Increase in LVEF, stable PCWP, increase in CI at maximum dobutamine | Pump off, 2 L/min |
| Dandel et al. (2005)[61] | LVEF ≥45%, LVEDD ≥55 mm | Pump off |
| Birks et al. (2006)[69] | LVEDD <60 mm, LVESD <50 mm, LVEF >45%, PCWP <12 mm Hg, CI >2.8 L/min/m², peak $VO_2$ >16 mL/kg/min, $V_E/VCO_2$ <34 | Pump off 15 min |
| Maybaum et al. (2007)[7] | Stable PCWP with reduction in flow | 2 L/min |

and eventual explant or transplant have demonstrated that many of these cellular, electrophysiological, and even neurohormonal processes can be improved and even reversed with MCS.[144] Although there are no accepted criteria for device explantation following myocardial recovery, functional studies with reduced or no device support using echocardiography and hemodynamic/metabolic parameters have been suggested by several groups when considering device explantation (Fig. 51-31).[144] The majority of data regarding successful explantation and outcomes with MCS as BTR come from patients for whom initial indication was for BTT.

The initial experience with early devices was encouraging. Among 111 patients who underwent device implantation for BTT with a mixture of both ischemic and dilated cardiomyopathy, only one patient of five experienced sustained myocardial recovery after explantation at 15 months; the remaining four patients either died or had another device implanted.[145] Nevertheless, by objective testing, half of patients with dilated cardiomyopathy and 17 percent with ischemic cardiomyopathy demonstrated at least partial myocardial recovery. Another group reported device explantation in 32 patients of 131 who underwent implantation for dilated cardiomyopathy. Among these 32 patients, 17 had sustained myocardial recovery at 3 years. Five-year survival among these patients was 78 percent.[146] In the LVAD Working Group Recovery Study, a multicenter prospective study of 67 patients with a mixture of ischemic and dilated cardiomyopathy, 6 patients met criteria and underwent explantation; 4 patients who underwent device implantation following acute heart failure enjoyed sustained myocardial recovery at 1 year, although the other two patients with chronic ischemic cardiomyopathy had clinically insignificant decreases in ejection fraction.[147]

With more modern devices, the experience has also been positive. With the HeartMate II, early experience among patients who underwent implantation as BTT reported a case of successful device explantation in one patient of 133 who underwent implantation.[58] In a subsequent report, 7 of 281 patients underwent device explantation following recovery of myocardial function at a median of 302 days (range 161–558 days).[59] Four of 43 patients reported by Frazier et al. were successfully weaned to explantation.[61] Among the European experience, 22 of 571 patients underwent explantation of the HeartMate II.[63] Use of the Jarvik 2000 as a BTR was reported in three patients who underwent explantation following 253, 407, and 683 days of support and were alive at 295, 446, and 567 days following explantation, respectively.[148] The INCOR device has been successfully explanted in 5 percent of patients in the worldwide experience of 212 patients.[81] Recovery following implantation with the DeBakey VAD has also been reported.[50]

One approach to BTR has been described using LVAD therapy for patients with dilated cardiomyopathy combined with maximum medical support including clenbuterol, a novel selective $B_2$ agonist (Harefield protocol).[149,150] Of 24 patients in the study, 11 patients underwent explantation after a median period of 388 days. Nine of these patients survived (one died postoperatively and one succumbed to cancer), and of the surviving patients, 100 percent were free from heart failure at 1 year and 89 percent at 4 years.[151] With this therapy, 46 percent of patients underwent successful explantation, compared with only 13 percent in the LVAD Working Group study. Currently, this protocol is being examined in an ongoing, multicenter clinical trial. The Harefield Recovery Protocol Study (HARPS) is a combination of maximal medical heart failure therapy along with device support and clenbuterol.

Future identification of patients who are most likely to have sustained myocardial recovery following device explantation and development of maximal adjunctive medical therapies will hopefully increase the number of patients who will benefit from MCS as a bridge to myocardial recovery.

## Bridge to Transplant

MCS has been most commonly used as a method in patients whose native heart function is not expected to recover, but who can benefit from medical optimization prior to undergoing heart transplantation. Currently the most common

indication for device implantation, both early and modern devices have demonstrated success for this indication.

Among the early devices, Frazier et al. demonstrated a benefit among transplantation candidates who received MCS as BTT therapy.[39] In this study, patients who were refractory to maximal medical support (inotropes with or without intra-aortic balloon counterpulsation) who underwent implantation of the HeartMate VE LVAD were compared to historical patients who received maximal medical support without device implantation. Following initiation of MCS, renal and hepatic function were significantly improved from predevice levels. Both survival prior to transplantation (71 vs 33 percent) as well as 1-year survival after transplantation (84 vs 63 percent) was significantly improved among patients who underwent BTT therapy compared to medical support alone. Further studies confirmed a benefit in survival to transplantation, but have differed with regard to potential benefit posttransplantation. One study showed no difference in survival, and two actually showed reduced survival; the impact of VAD on the pre-and posttransplant recipient may not be fully understood in the absence of a prospective, randomly controlled trial among patients awaiting cardiac transplantation.[152–154] One potential explanation for the differences in posttransplant survival may have to do with patient selection. Patients with more severe heart failure decompensation refractory to medical intervention have been shown to have worse outcomes with up to three times the mortality in the pretransplant period compared to those patients with less severe myocardial dysfunction and those with response to medical heart failure therapies.[155]

Recent trials with newer-generation devices have also shown a benefit from MCS prior to transplantation. Miller et al. reported a clinical trial of the HeartMate II device among 133 patients with end stage heart disease awaiting cardiac transplantation.[58] The main outcome of this trial was successful transplantation, continued support, or cardiac recovery at 180 days. Seventy five percent of patients reached this endpoint, including 56 who proceeded to transplantation and 43 who remained active on the transplant list. Overall survival was 75 percent at 6 months and 68 percent at 1 year. A follow-up study that reported on 281 of the 469 patients who underwent HeartMate II implantation while awaiting cardiac transplantation also showed excellent results at 18-month follow-up.[59] During this time period, 79 percent of patients underwent transplantation or had continued device support. Survival at 18 months was 72 percent. Lahpor reported the European experience with the HeartMate II as BTT and of 571 patients; 23 percent underwent transplantation and 42 percent had ongoing support at 6 months.[63] Lorforte reported a 50 percent transplantation rate, including18 patients who were supported for a mean of 217 days and achieved posttransplant survival rate of 66.6 percent.[64,77]

Goldstein reported the international experience with the DeBakey VAD implanted in 150 patients for BTT.[50] Among these patients, there was a cumulative support time of 30.4 patient years, with 55 percent proceeding to transplantation (62 patients) and 19 patients remaining on the active transplant list (19 patients). The longest support time was 492 days, and 13 percent of patients were on support for greater than 6 months.

Initial reports of the Jarvik 2000 in 22 patients were also good; 13 patients proceeded to transplantation and another two were active on the waiting list with an average support time of 67 days.[54] In another group, 22 patients who received the Jarvik 2000 were supported for a mean of 280 days with 7 patients receiving a heart transplant, 4 remaining on the list, and 3 with myocardial recovery.[148] Siegenthaler reported on 83 patients who underwent implantation of the Jarvik 2000, with a mean support time of 159 days and a maximal support time of 2.7 years.[55]

Wieselthaler reported the first experience with the Heartware device in 23 patients who achieved a mean support time of 167 days.[73] By the 180-day endpoint, 2 patients underwent transplant and 19 patients continued support for longer than 6 months with 6- and 12-month survivals of 91 and 86 percent. The ADVANCE study reported the BTT experience among 140 patients and compared them to patients who underwent implantation of other commercially available devices during the same time period.[79] The survival was 92 and 91 percent at 1 year, which were comparable to the alternative devices.

The use of the VentrAssist device as BTT was promising among the 400 patients who were implanted with this device; 36 to 40 percent of patients underwent transplantation and 42 to 44 percent had continued support, but due to technical and financial difficulties this device was ultimately discontinued.[68,69]

The Syncardia (CardioWest) TAH has also shown good results as BTT therapy. Among the 81 patients in a clinical trial, 79 percent of patients went on to successful transplantation with 1- and 5-year survivals for patients who underwent transplantation of 86 and 64 percent, respectively.[85] When compared to the control arm (no MCS), both survival to transplantation and survival posttransplant were improved.[85] Another experience with 127 patientsreported up to 74 percent of patients who successfully proceeded to transplantation.[86]

BTT has been reported to be successful with the INCOR device; 31 percent of patients were successfully bridged to transplant and another 20 percent remained active on the list out of the 212 patients who underwent implantation worldwide.[81]

Although these data are promising, determination of the optimal patient, device, and timing of implantation will be crucial to ensure the best outcomes among these patients.

## Destination Therapy

MCS is often considered as DT for patients with severe, end stage heart failure who are not expected to recover native myocardial function and who are not candidates for cardiac transplantation. Several landmark clinical trials of MCS for DT using early devices are of historic interest and established

DT, destination therapy; REMATCH, Randomized Evaluation of Medical Assistance in the Treatment of Congestive Heart Failure; CUBS, Clinical Utility Baseline Study; INTREPID, Investigating of the Non-Transplant Eligible Patients who are Inotrope Dependent; LVAD, left ventricular assist device.

**FIGURE 51-32** Published results from clinical trials of mechanical circulatory support for DT. (Reproduced with permission from Lietz K, Miller LW. Destination therapy: Current results and future promises. *Semin Thorac Cardiovasc Surg* 2008;20:225–233.)

this use for MCS (Fig. 51-32).[156] Newer studies using modern devices have also been published and further strengthened this application for device therapy.

The landmark Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial was the first to compare survival with MCS with the HeartMate VE LVAD to that of optimal medical management.[136] It demonstrated improved survival in patients supported with LVADs compared to medical management alone (1-year survival: 52 vs 25 percent, 2-year survival: 23 vs 8 percent, respectively) and validated the use of these devices for long-term support in patients who were not candidates for transplantation. A follow-up study, the post-REMATCH group, compared patients who received the newer HeartMate XVE LVAD and again demonstrated an increase in 1- and 2-year survivals of 56 and 31 percent compared to their control group of 25 and 8 percent (Fig. 51-33).[157]

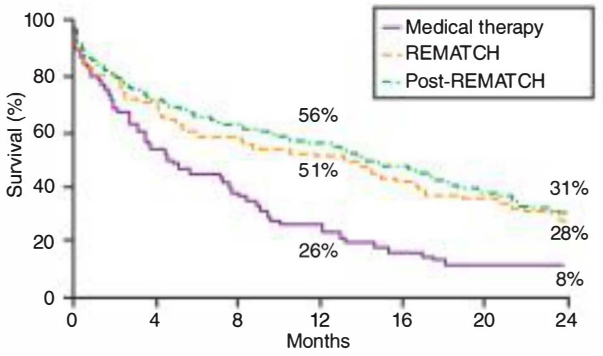

**FIGURE 51-33** Survival of patients undergoing DT in the REMATCH and post-REMATCH groups compared to medical therapy alone. (Reproduced with permission from Lietz K, Miller LW. Destination therapy: Current results and future promises. *Semin Thorac Cardiovasc Surg* 2008;20:225–233.)

Following the REMATCH trial, results of the Investigation of Nontransplant-eligible Patients Who Are Inotrope Dependent (INTrEPID) trial were published.[158] This trial included patients who had all failed inotropic management, and compared those who received LVAD therapy with a Novacor device to those patients who elected not to receive an LVAD device. Despite the fact that this cohort of patients was even sicker than those in the REMATCH trial, there was a significant improvement in survival with LVAD therapy compared to medical therapy alone (6-month survival: 46 vs 22 percent, 12-month survival: 27 vs 11 percent, respectively.

The lessons from REMATCH demonstrated that there is a cohort of patients who benefit from LVAD support over medical therapies. These include inotrope-intolerant patients (e.g., ventricular arrhythmias), patients requiring complex and/or multistage operations, patients with life-threatening coronary lesions not amenable for coronary revascularization, and patients with severe end-stage heart failure. These risks must be balanced with the survival benefit provided by mechanical support. Hence, it is important to identify high-risk candidates who might be optimized prior to device implantation to avoid associated morbidity and mortality.[136]

A European trial, the CUBS trial reported an experience with the LionHeart 2000 ventricular assist system.[159] The survival from this trial was not as good as previously published trials; however, the patients in this trial were generally sicker than those included in the device implant group for the landmark REMATCH trial or later studies. Survival at 1 and 2 years following initiation of MCS for DT were 39 and 22 percent, respectively.

The first trial to compare two different devices for DT was a multicenter clinical trial in which 200 patients who were not eligible for transplant were randomized to receive either a pulsatile HeartMate XVE or nonpulsatile HeartMate

II for DT.[60] The results of this trial demonstrated that the HeartMate II group achieved superior outcomes comparedto the HeartMate XVE group in terms of stroke, reoperation free survival (46 vs 11 percent), and overall survival (58 vs 24 percent) at 2 years. In addition, adverse events (device replacement, infection, right heart failure, arrhythmia, respiratory failure, and renal failure) were less common with the HeartMate II device compared to the HeartMate XVE. This multicenter trial supported the use of the HeartMate II as DT for end stage heart failure. Other studies that support this indication came from Frazier et al., who reported 17 patients with a longest support time of over 700 days, Lahpor et al. who reported 119 patients with a mean duration of support of 236 days, and Granfeldt et al. who reported a patient with over 3 years of support.[61,63,160]

Other devices have also shown to be useful as DT. Siegenthaler reported successful use of the Jarvik 2000 as DT in 19 patients with a mean support time of 445 days and maximal support time of 4.9 years.[55] The longest surviving patient with the Jarvik 2000 has been alive for over 6 years.[53] Among the 14 AbioMed TAH implants, the majority were alive 2 months following implantation with the longest survivor living formore than 1 year.[88,89] Prior to its removal from the marketplace, the VentrAssist device also showed success for DT; among 16 patients who received a device as DT, 1- and 2-year survivals were 80 and 60 percent, respectively.[68] The Heartware device is currently being investigated in the ENDURANCE trial as DT.

## SUMMARY

MCS is used in patients whose heart failure cannot be ameliorated with medical management alone. Devices have evolved from early paracorporeal pulsatile devicesto modern intracorporeal pulseless axial flow models and even TAHs capable of biventricular support. Indications for clinical use include BTR for patients in whom myocardial recovery is anticipated, BTT prior to cardiac transplantation, and DT for patients who have contraindications to transplantation.

## MECHANICAL CIRCULATORY SUPPORT BOARD REVIEW QUESTIONS (CHAPTER 51)

1. Which is not a currently accepted use for mechanical circulatory support?
   A. As a method to optimize tissue perfusion and maintain adequate cardiac output while awaiting definitive cardiac transplantation (bridge to transplant)
   B. As lifelong permanent therapy for refractory end-stage heart failure (destination therapy)
   C. As temporary support to unload the heart and allow myocardial recovery from a potentially reversible insult (bridge to recovery)
   D. As temporary support while determining other organ suitability for transplant (bridge to donation)
   E. As temporary support prior to determination of candidacy for permanent mechanical circulatory support (bridge to bridge)

2. Which of the following is a contraindication to mechanical circulatory support?
   A. Need for both right and left heart support
   B. Dialysis-dependent renal failure
   C. Moderate aortic insufficiency
   D. Atrial fibrillation
   E. Patent foramen ovale

3. Which of the following is true regarding permanent mechanical circulatory devices?
   A. Device placement usually is performed on cardiopulmonary bypass.
   B. The inflow cannula is typically inserted into the right superior pulmonary vein and the outflow cannula in the aortic arch.
   C. Postoperative anticoagulation with Coumadin is optional for most devices.
   D. The device is positioned within the peritoneum.
   E. The drive line should be tunneled out through the left lower quadrant.

4. During LVAD implantation, which echocardiographic plane is best for assessing the mitral valve?
   A. Axial
   B. Coronal
   C. Double-oblique
   D. Vertical long axis
   E. Short axis

5. Which of the following is correct regarding device-specific complications of mechanical circulatory support?
   A. Transfusion is required in less than 50 percent of patients.
   B. Suppressive long-term antibiotics are necessary to reduce infection.
   C. Thromboembolism is the most common complication.
   D. Overall infection rates are about 30 percent.
   E. Postimplant organ failure occurs in less than 10 percent.

## ANSWERS

1. **Answer: D.** There is no indication for implantation of mechanical circulatory support in order to maintain an individual for possible organ donation. Current indications for mechanical circulatory support include bridging temporary devices to more permanent devices, bridge to transplantation, bridge to recovery, and destination therapy.
2. **Answer: B.** Patients with renal failure are not candidates for mechanical circulatory support. Biventricular failure is an indication for mechanical support. Moderate aortic insufficiency and patent foramen ovale should both be corrected at the time of initiation of circulatory support. Atrial fibrillation and other dysrhythmias should be aggressively treated, but are not contraindications to mechanical support.
3. **Answer: A.** Placement of a permanent LVAD usually required cardiopulmonary bypass for insertion of the uptake cannula into the left ventricular apex. Insertion of the uptake cannula into the right superior pulmonary vein is performed for temporary LVAD placement. Postoperative anticoagulation with Coumadin is the rule for most devices. The devices should ideally be placed in a preperitoneal pocket to avoid injury to intra-abdominal organs. The drive line exits the skin in the right upper quadrant.
4. **Answer: D.** The vertical long axis view provides the optimal plane for mitral valve evaluation. The axial plane is best for the overall heart view and extracardiac structures. The coronal plane visualizes the left ventricular outflow tract and aortic valve. The double-oblique plane is best for the arch and evaluation of dissection. The short-axis plane is best for assessing wall motion abnormalities.
5. **Answer: D.** Meticulous sterile technique and improvements in implantation procedures has reduced overall infection rates to about 30 percent. Transfusion of any blood product is necessary in over 75 percent of patients. Suppressive long-term antibiotics are not indicated after device implantation. Bleeding, not thromboembolism, is the most common complication. Postimplant organ failure occurs in 10 to 30 percent of patients.

# 52 Surgical Ventricular Remodeling

*Clinton D. Kemp*
*John V. Conte*

**KEY CONCEPTS**

- Epidemiology
  - Congestive heart failure (CHF) is the most prevalent medical problem in Western society as the leading cause of death in the United States. Ischemic cardiomyopathy (ICM) is the leading cause of CHF, affecting 75 percent of patients with CHF.
- Pathophysiology
  - ICM is generally caused by a full-thickness myocardial infarction (MI), followed by ventricular remodeling. This remodeling process can result in progressive dilation of the ventricle, leading to an increase in the end-diastolic diameter and volume, an increase in left ventricular wall stress and oxygen demand, a loss of the left ventricle's natural elliptical shape with the development of a more rounded form, the development of mitral insufficiency and, ultimately, a worsening of global systolic function.
- Clinical features
  - Progressive CHF due to ICM results in debilitating congestive symptoms, including dyspnea, fatigue, peripheral edema and, in its end stages, acute and/or chronic multisystem organ failure. Classically, patients are candidates for surgical ventricular remodeling (SVR) if they have had an anterior MI, have a large area of akinesis or dyskinesis, and have clinical evidence of CHF.
- Diagnostics
  - Preoperative diagnostics include cardiac catheterization with coronary angiography. Other potentially useful diagnostics include myocardial viability and magnetic resonance imaging studies.
- Treatment
  - The surgical goals of SVR include complete revascularization of all viable territories, exclusion of akinetic and dyskinetic segments with a concomitant reduction in the size of the nonfunctioning anteroseptal portion of the heart, recreation of the elliptical shape of the heart, and repair of any valvular incompetence by valve repair or replacement.
- Outcomes/prognosis
  - SVR has been shown to improve ventricular size, morphology, left ventricular ejection fraction (EF), stroke-volume index, endocrine markers of CHF, ventricular energetics, ventricular synchrony, and mechanical efficiency. Clinically, it results in improved functional capacity (New York Heart Association class) and an excellent 5-year survival in very sick patients. Further study and experience are needed to optimize patient selection and timing for surgical intervention as well as to better define the mechanistic basis behind the beneficial effects of SVR.

## INTRODUCTION

Congestive heart failure (CHF) is a major medical problem facing Western society today. It is the leading cause of death in the United States, representing over one-quarter of all deaths and is expected to become even more significant in the years ahead.[1] The incidence of new CHF cases are on the rise as more than 400,000 new cases per year continue to add to the over 5 million people living with CHF in the United States.[1] Ischemic cardiomyopathy (ICM) is the leading cause of CHF, affecting some 75 percent of patients with this condition.[2,3] Medical and surgical therapies have been shown to be effective in improving survival and quality of life in CHF patients.[4] Coronary artery bypass grafting (CABG) has been shown to be effective in some patients with ICM, but heart transplantation and left ventricular assist devices are more effective in patients with advanced heart failure.[5] Surgical ventricular remodeling (SVR) is a surgical procedure whose

roots arise from the surgical treatment of left ventricular aneurysms. Also known as surgical ventricular restoration, endoventricular circular patch plasty, and the Dor procedure, SVR has been shown to be an effective treatment for select patients with ICM. In this chapter we will review the pathophysiological basis and the clinical experience with SVR.

## PATHOPHYSIOLOGY

The pathophysiology of ICM is related to the changes that occur following full-thickness myocardial infarction (MI). Following infarction, the left ventricle (LV) undergoes a well-described process of ventricular remodeling.[6] Left unchecked, this process can lead to a progressive dilation of the ventricle, resulting in an increase in the end-diastolic diameter and volume, an increase in LV wall stress and oxygen demand, a loss of the ventricle's natural elliptical shape with the development of a more rounded contour, the development of mitral insufficiency and, ultimately a worsening of global systolic function.[6,7] The development of mitral regurgitation is due to factors specific to ventricular remodeling as well as unrelated leaflet issues. They include annular dilation due to global ventricular enlargement, restricted leaflet motion and reduced coaptation due to leaflet tethering, or involvement of the papillary muscles with the infarction. These factors combine to prevent or limit leaflet coaptation in the proper plane, resulting in central regurgitation. Superimposed leaflet pathology can worsen the functional regurgitation.

Postinfarction dysfunction is further affected by both the electrical and mechanical dyssynchrony that develops following infarction.[8] The concept of electrical dyssynchrony suggests that abnormalities in the conduction system following infarction result in differential timing of left and right ventricular contraction. This dyssynchronous contraction results in diminished overall LV function, a condition treated, in appropriate circumstances, with biventricular pacing. Mechanical dyssynchrony is a phenomenon of impaired LV function caused by nonuniform contraction, relaxation, and filling of the ventricle due to juxtaposed areas of akinesis, dyskinesis, and hypokinesis alongside normal areas. This has been associated with reduced survival.[8,9]

The prognosis of patients with ICM is related to the size of the LV and the impact that remodeling has had on the function of the remote noninfarcted zones.[7,10,11] Infarction results in a disruption of the normal spiral arrangement of myocardial fibers.[12] The normal spiral architecture helps to resist deformation, direct blood flow toward the aortic valve, and optimize contractile efficiency. Loss of this architecture leads to a more spherical ventricle. Loss of an elliptical shape leads to a progressive reduction in contractile force, ultimately leading to death.[8,9] Since the seminal work of White, studies ranging from GUSTO to STICH have all shown that LV size is a surrogate marker of mortality in CHF.[10,12]

Coronary artery revascularization, details of which are presented elsewhere in this book, has been shown to improve survival in both normal and abnormal ventricles.[5] Improved blood flow, however, cannot improve the function of the scarred, noncontractile areas of the heart, reduce dyssynchrony, or reverse the morphological changes of infarction. Surgical techniques have been developed to arrest the progression and reverse the morphologic changes induced by the pathologic process of postinfarction ventricular remodeling. Such techniques are commonly referred to as SVR. SVR is not one techniquebut several, all of which have the same surgical goals: to reduce the size of the LV and restore a more normal elliptical shape to these enlarged spherical hearts to improve cardiac function. SVR is often performed in conjunction with coronary artery revascularization and mitral valve repair/replacement. In this chapter, these techniques are presented and the clinical outcomes discussed.

## HISTORY

The history of the surgical approach to postinfarction remodeling begins with the approach to postinfarction LV aneurysms. Denton Cooley was the first to attempt to change the shape of the ventricle when he performed the first linear LV aneurysmectomy on cardiopulmonary bypass (CPB) to treat a calcified LV aneurysm in 1958.[13]

Many other techniques and approaches were developed over the years to treat postinfarction ventricular aneurysms.[14] Fontan originally described the use of endoventricular purse-string sutures to reduce the size and reapproximate the wall of the LV.[15] Jatene developed a technique of septoplasty and modified linear closure in the early 1980s.[16] At the same time, Vincent Dor and colleagues introduced the technique of endoventricular circular patch plasty, which later, in 1985, came to bear his name.[17] His approach was unique in that it approached akinetic areas and dyskinetic aneurysms equally. He later began to apply this technique to treat CHF and altered the way in which changes in ventricular morphology are approached. Cooley and colleagues later utilized a similar technique for aneurysmal resection by patching the anterior wall from within the ventricle but without the encircling purse-string suture to reduce the volume of the anterior wall of the LV.[18]

The concept of reconstructing the ventricle to a prescribed size based on the patient's body size was introduced by Dor and popularized by Menicanti.[19] The best methodology to determine the appropriate size of the reconstructed ventricle has yet to be determined. Some surgeons base it on the enlarged end-diastolic dimensions and others by indexed body surface area.[19] Additional technical approaches that merit mention include a linear closure and septoplasty approach described by Mickleborough, a modified linear closure technique popularized by Guilmet in which there is direct endoventricular apposition of the lateral wall to the septum to create a new anterior wall, and a concentric purse-string or "cerclage" technique followed by linear closure

**TABLE 52-1: Indications for Surgical Ventricular Remodeling**

| End-systolic volume index >60 mL/m² |
| Candidate for valve repair/replacement |
| Candidate for revascularization |
| Good right ventricular function |

utilized by McCarthy.[20,21] The end result of two decades of surgical innovation are four techniques used for ventricular remodeling procedures today.

## INDICATIONS FOR SURGERY

Classically, patients are candidates for SVR if they have had an anterior MI, have a large area of akinesis or dyskinesis, and have clinical evidence of CHF. Specific characteristics of patients who have successfully undergone SVR are shown in Table 52-1. Ideal candidates have akinesis/dyskinesis in the anteroseptal area, have retained function of the basilar and lateral portions of the heart, and have good right ventricular function. They should also be candidates for revascularization and mitral valve repair if needed. Included in many clinical series of SVR are patients who have had anterior infarctions with areas of akinesis or dyskinesis with lesser degrees of ventricular enlargement and CHF. The indication for surgery in these patients is angina in other territories with the need for coronary artery revascularization. In such patients, the goal of therapy is to prevent dilation and the clinical development of CHF, which is an inevitable part of postinfarction remodeling. Relative contraindications are shown in Table 52-2. Many patients have additional cardiac conditions that will necessitate repair or replacement, and they should be candidates for surgical repair of any lesion that exists. Success has also been demonstrated in groups of patients with more complex pathologies such as multiterritory infarctions, truly advanced end-stage CHF, and the need for multiple concomitant procedures.[22,23]

| Unreconstructable coronary artery disease |

## SURGICAL APPROACHES

The surgical goals of SVR include complete revascularization of all viable territories, exclusion of akinetic and dyskinetic segments with a concomitant reduction in the size of the nonfunctioning anteroseptal portion of the heart, recreation of the elliptical shape of the heart, and repair of any valvular incompetence by valve repair or replacement.

## SURGICAL TECHNIQUE

Several different surgical approaches are used to achieve the goals stated above. Common among each of the approaches is the median sternotomy incision, which is standard in cardiac surgery. The surgical procedure begins with standard arterial and venous cannulation for CPB. If mitral valve repair or replacement is a strong possibility, cannulation of both the inferior and superior venae cavae is recommended. The LV can be vented directly through its apex, through the left atrium via the right superior pulmonary vein, or through the aortic root. Prior to systemic heparinization, femoral arterial access is obtained to make the later placement of an intra-aortic balloon pump easier if necessary. Since concomitant CABG is usually performed, a standard approach for CABG is utilized, including myocardial protection.

Once the patient is on CPB, the sequence of procedures performed is a matter of personal preference. Most commonly, CABG is performed first. Once this is accomplished, the SVR or mitral valve replacement (MVR) can be performed next.

The mitral repair can be done utilizing any technique preferred. An intraventricular repair as described by Menicanti is done through the ventriculotomy prior to performing the SVR.[19] Our standard approach is to perform a reduction posterior annuloplasty through a standard interatrial groove incision prior to performing the SVR to avoid the remote possibility of disrupting our ventricular closure.

In the arrested heart with the LV vented, the LV will often collapse, demonstrating the area of thinned-out scar. If this does not happen, it may be due to a partial-thickness infarction. The absence of collapse does not contraindicate SVR and simply means that revascularization occurred early enough to prevent full-thickness infarction.

The technique employed at Hopkins is a variation of the endoventricular circular patch plasty popularized by Vincent Dor. It is depicted in Figures 52-1 to 52-7. An incision is made into the anterior wall of the LV through the area of scar. In a typical anterior infarction, the incision is extended distally to the apex and proximally parallel to the course of the left anterior descending coronary artery until normal muscle is encountered. Retention sutures are placed into scar to aid in achieving and maintaining exposure.

The ventricle is inspected and any thrombus is removed. During inspection of the ventricle, the extent as well as the transmurality of the scar is noted. A transition zone between infarcted and noninfarcted muscle is often palpable. This

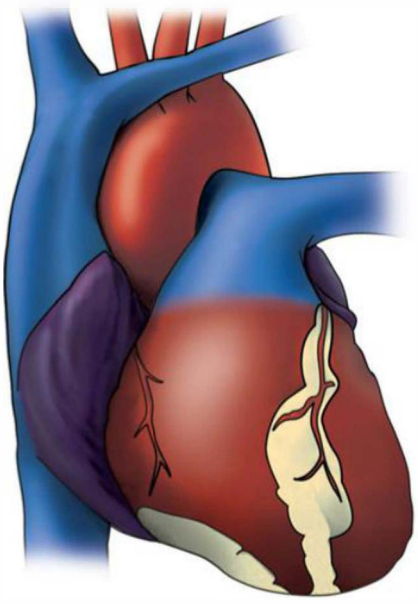

FIGURE 52-1 Normal heart.

is particularly evident with full-thickness infarctions but is notably absent in some patients who have received thrombolytics or percutaneous revascularization prior to widespread cell death. These patients may demonstrate a mosaic pattern of ventricular scarring. Such ventricles often show akinesis rather than dyskinesis. The presence or absence of a clear

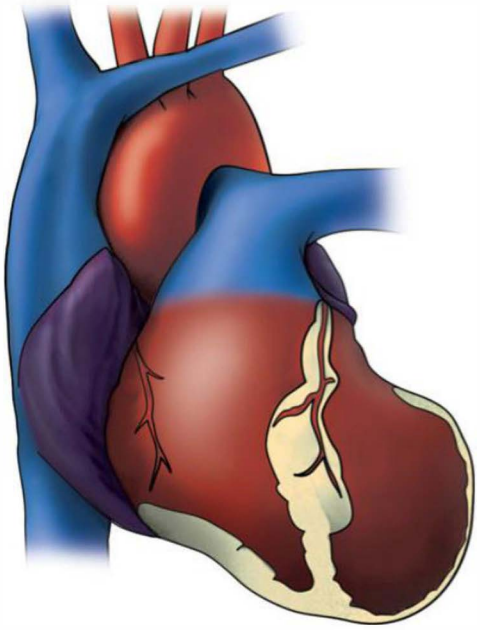

FIGURE 52-2 Heart with thinned akinetic ventricle following anterior wall myocardial infarction.

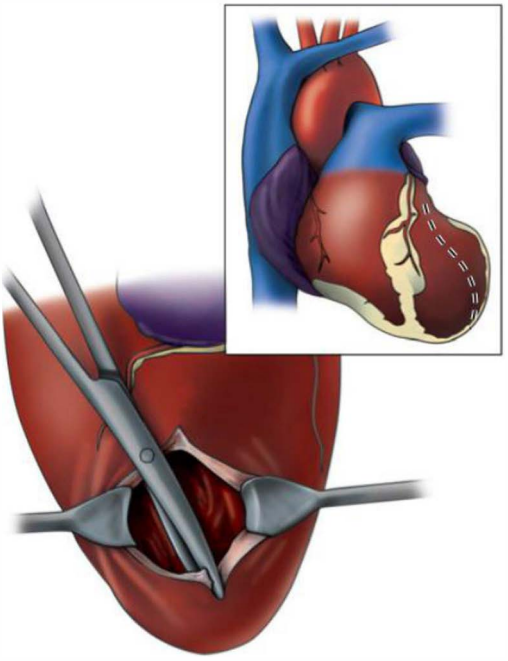

FIGURE 52-3 Anterior ventriculotomy parallel to the course of the left anterior descending coronary artery.

transition zone is not known to be of clinical significance. The differences in the various operations are apparent from this point forward in the operation.

At this point in the procedure with many techniques, an encircling purse string of 2-0 polypropylene suture is placed along the anterior border of the sizing device. Placement of the purse-string, often called the "Fontan stitch," is one of the key steps in the operation. It chooses the new apex of the heart and defines the outline of the new anterior wall. Selecting the location of the purse strings is usually done by personal preference. It can be done in a measured fashion, using one of several commercially available sizing devices, by selecting a site based on experience or proximity to a landmark such as the papillary muscles, or at the border of infarcted and noninfarcted tissue. Use of the "border zone" was most commonly recommended before the development of commercially available devices. If a sizing device is used, a variety of methods of determining the size of the device to be used have been recommended (Fig. 52-4). Our device is selected based on a volume of 50 to 60 mL/m$^2$ body surface area. Obese patients will have the volume titrated down slightly and cachectic patients will have it titrated up.

Once the anterior wall is encircled with the purse-string suture, it is reconstructed utilizing a variety of techniques. It is important to place the purse-string in such a fashion as to create an elliptical ventricle (Fig. 52-5). A patch of Dacron is used if the remaining defect is greater than 2 to 3 cm long. An oval patch is cut to the appropriate size and sutured in place, closing the defect. Care is taken to place the patch sutures around the anterior purse string. The patch may be

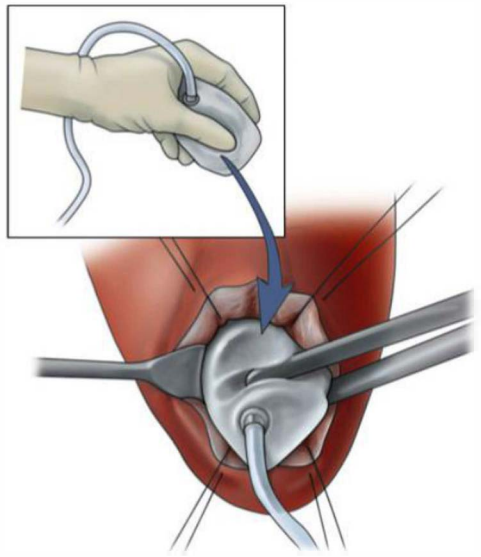

FIGURE 52-4 Insertion of ventricular sizing device following placement of retention sutures for exposure. The volume of the sizing device is selected on the basis of body surface area (50–60 mL/m²).

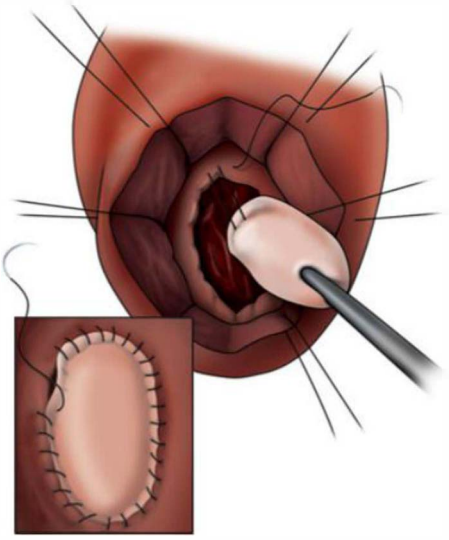

FIGURE 52-6 Patch closure reconstruction of anterior wall for residual ventriculotomy openings of greater than 3 cm. Smaller residual defects are closed primarily.

sutured using a continuous or interrupted technique. Prior to completing the patch, the left ventricular vent is shut off, allowing the ventricle to fill with blood and forcing air to escape the ventricle through the partially completed closure (Fig. 52-6). After the patch is sutured into place, a linear closure is performed superficial to the patch or purse-string. Horizontal mattress sutures, buttressed with bovine pericardium, are used as a first layer of closure. The second layer is a continuous running stitch of 2-0 polypropylene (Fig. 52-7). If the defect is moderate in size but not large enough for

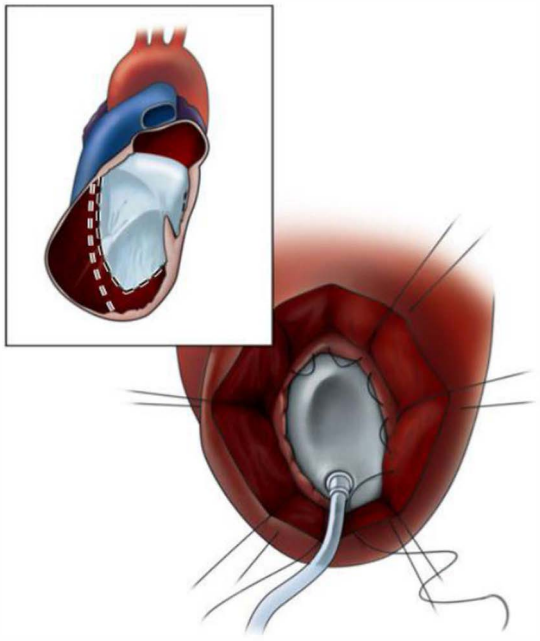

FIGURE 52-5 Placement of purse-string suture to define margins of reconstruction of anterior wall.

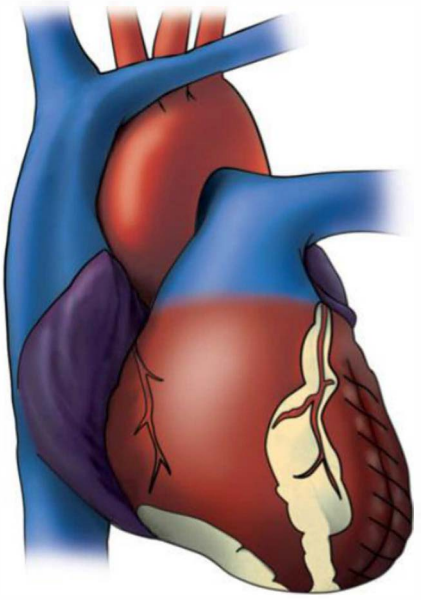

FIGURE 52-7 Two-layer closure of ventriculotomy. Horizontal mattress sutures are used for the first layer, followed by continuous running suture for the second layer.

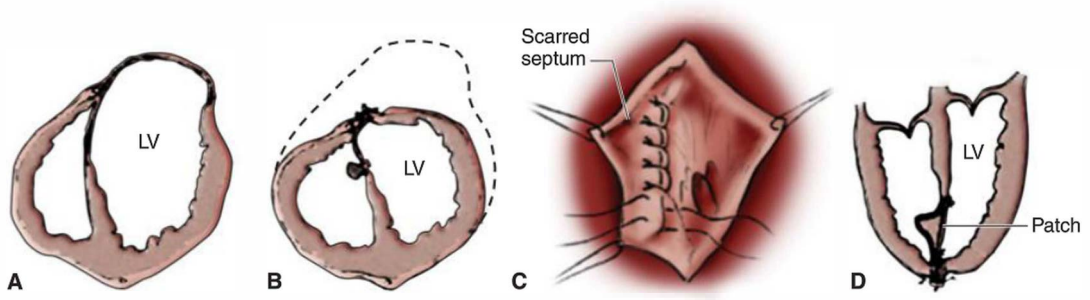

**FIGURE 52-8** Linear closure of Guilmet. The deep scar of the septum is sewn directly to the deep scar of the lateral wall internally. (Adapted from Mukaddirov M, Demaria RG, Perrault LP, et al. Reconstructive surgery of postinfarction left v entricular aneurysms: Techniques and unsolved problems. *Eur J Cardiothorac Surg* 2008;34:256–261. Copyright Elsevier.)

patching, the ventricle can be reapproximated superficial to the purse-string using a linear closure, usually reinforced.

An alternative technique advocated by Linda Mickleborough employs a modified linear closure and patch septoplastyto accomplish the same SVR surgical goals. This technique uses the same anterior ventriculotomy approach to expose the septum and anterior wall. This technique employs a more traditional linear closure to exclude the akinetic or dyskinetic areas of the anterior wall. In addition, the dilated, fibrotic areas of the infarcted septum are addressed by either including the septum in the linear closure of the anterior wall or patching the septum and including the patch in the linear closure.[24]

A technique of multiple purse strings is employed by Pat McCarthy. Also called the cerclage technique, it begins as the previous two techniques. Once the anterior wall purse string is placed and tied, additional purse strings are placed a few millimeters superficial to the previous purse string. This continues anteriorly until the final remaining defect is small and is closed with a standard linear closure.[25]

A modified septoplasty technique, employed by Jatene, aimed to reduce the volume of the infarcted septum in conjunction with a patch or primary closure. This technique also begins in the same way as other SVR procedures. An anterior encircling purse-string is placed to define the borders of the anterior wall, as is done in some of the other SVR techniques. The distinguishing characteristic of this technique is the placement of mattress sutures in the septum to reduce the horizontal length of the septum. Once the septal reduction is performed, the anterior encircling purse-string is tied and the anterior wall closed primarily or with a patch.[16]

A final technique utilizes an internal linear closure described by Guilmet.[26] With this technique, the deep scar of the septum is directly sewn to the deep scar of the lateral wall internally. This excludes the more superficial scar and aligns the remaining septal and lateral scar tissue for a linear closure (Fig. 52-8).

A word should be mentioned about performing the SVR with the heart beating. One advantage is that poorly functioning, often ischemic ventricles are not further injured during the period of cardiac arrest. Another is that the degree of mitral regurgitation and the result of mitral repair can be assessed in a beating heart, which is felt by some to be advantageous. A final advantage is that it allows the border between contracting and noncontracting segments of the heart to be seen more clearly from within the ventricle, which may aid in performing the SVR. The disadvantage is that it is much more difficult to place the sizing device on the mitral annulus and keep it there to allow accurate placement of sutures. This disadvantage can be partially compensated for by tracing the outline of the margins of the sizer on the endocardium and then deflating the sizer. In retrospective studies, SVR performed on the beating heart or with cardioplegic arrest has demonstrated no differences in outcomes. However, the novice may be aided with cardiac arrest until experience is gained. D'Onofrio reported a retrospective review of 588 patients who underwent SVR with normothermic CPB and a beating heart or with hypothermic CPB and cardioplegic arrest and found no difference in outcome with regard to LV volume reduction, ejection fraction (EF), improvement NYHA class, 30-day mortality, or long-term mortality between the groups.[27] An analysis of the 1188 patients in the RESTORE (Reconstructive Endoventricular Surgery Torsion Original Radius Elliptical) group also showed no difference in outcomes when patients who underwent beating heart SVR were compared to those who underwent hypothermic CPB and cardioplegic arrest.[28]

## PHYSIOLOGICAL CHANGES AFTER SURGICAL VENTRICULAR REMODELING

The goal of SVR is to recreate a normal-sized ventricle from the remaining functional myocardium while at the same time eliminating akinetic or dyskinetic segments. Several groups have reported physiological data from patients who have undergone SVR in order to better understand the post-SVR physiology.[29–43] Preoperatively, those with MR have more severe physiological dysfunction, with larger areas of

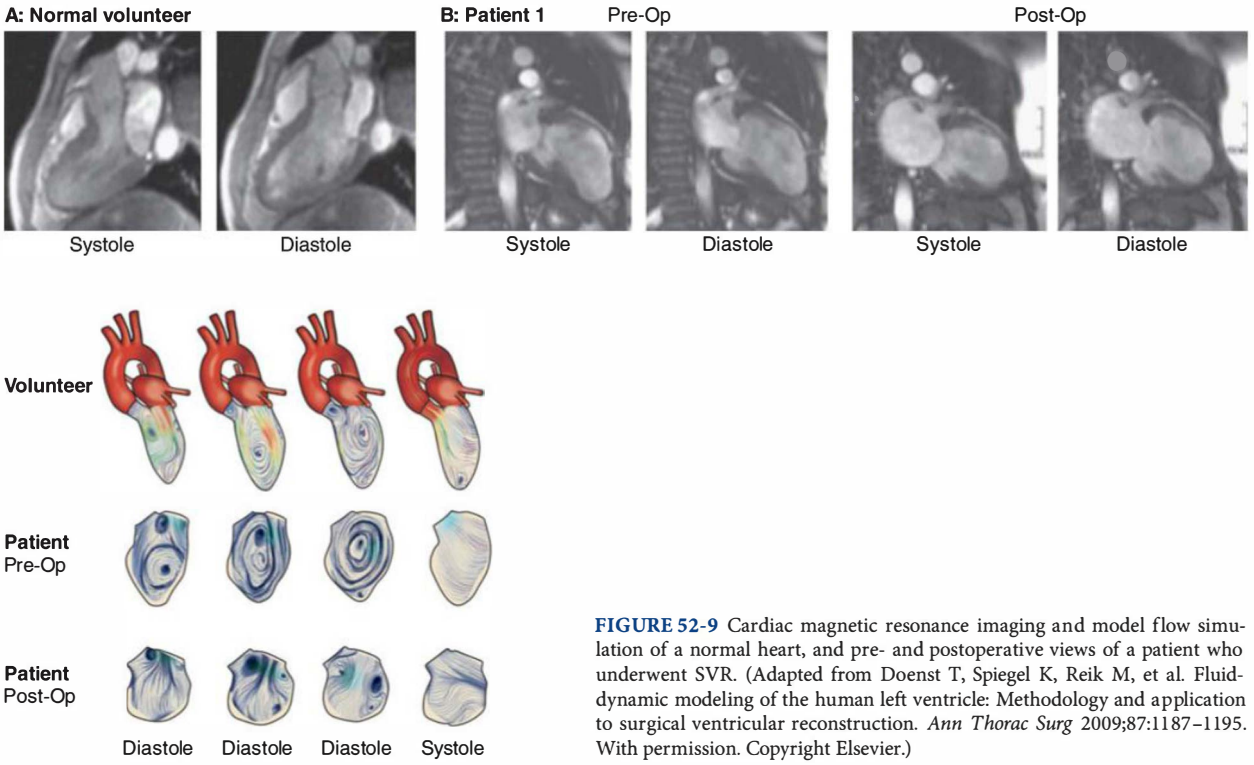

**FIGURE 52-9** Cardiac magnetic resonance imaging and model flow simulation of a normal heart, and pre- and postoperative views of a patient who underwent SVR. (Adapted from Doenst T, Spiegel K, Reik M, et al. Fluid-dynamic modeling of the human left ventricle: Methodology and application to surgical ventricular reconstruction. *Ann Thorac Surg* 2009;87:1187–1195. With permission. Copyright Elsevier.)

akinesia, greater LV volumes, and lower LVEF compared to those without MR.[29] SVR results in a decrease in LV end-diastolic and systolic volumes and percentage of akinetic/dyskinetic myocardium, and an increase in LVEF both at early and late time points following this procedure.[30,31] Torsional mechanics of the LV, specifically of the apex, are impaired among patients with ICM, processes that can be improved following SVR, especially for those patients who have significant preoperative dysfunction.[32] Recently, Doenst et al. reported a fluid-dynamic model that utilizes pre- and postoperative cardiac magnetic resonance imaging to evaluate ventricular flow in patients who have undergone SVR (Fig. 52-9).[33]

DiDonato et al. analyzed the LV shape in patients with ICM using a Fourier (radius of curvature) analysis to determine if the preoperative shape and wall motion abnormalities of the LV following anterior infarction influences outcomes after SVR.[34] Utilizing preoperative echocardiographic images in the 30° right anterior oblique (RAO) axis to examine wall motion and LV shape, three types of LV abnormalities in postinfarction ventricles were characterized (Fig. 52-10). Type 1 represents a true aneurysm with two hinge points, or borders between functional and akinetic/dyskinetic myocardium. Type 2 has one such hinge point, and type 3 is representative of ischemic dilated cardiomyopathy without any hinge points. The amount of functional myocardium is correlated to this classification with type 1 having the most and type 3 the least working myocardium. Not surprisingly, survival was highest among those patients with type 1 morphology, intermediate among those with type 2, and lowest among those with type 3 morphology preoperatively.

One of the most interesting studies of the effect of SVR on cardiac function was performed by DiDonato and colleagues at the Center Cardiothoracique de Monaco.[21] They looked at 30 patients undergoing SVR who did not have electrical dyssynchrony by QRS definition but did have mechanical dyssynchrony. Pressure/volume (P/V) loops were obtained with intraventricular micromanometer-tipped catheters a nd

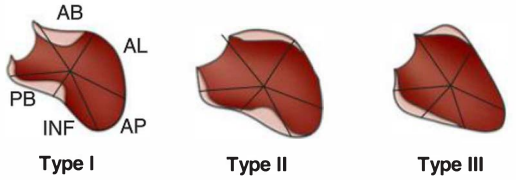

**FIGURE 52-10** Echocardiographic classification of the left ventricle in patients with ICM, (Adapted from DiDonato M, Castelvecchio S, Kukulski T, et al. Surgical ventricular restoration-left ventricular shape influence on cardiac function, clinical status, and survival. *Ann Thorac Surg* 2009;87:455–462. With permission. Copyright Elsevier.)

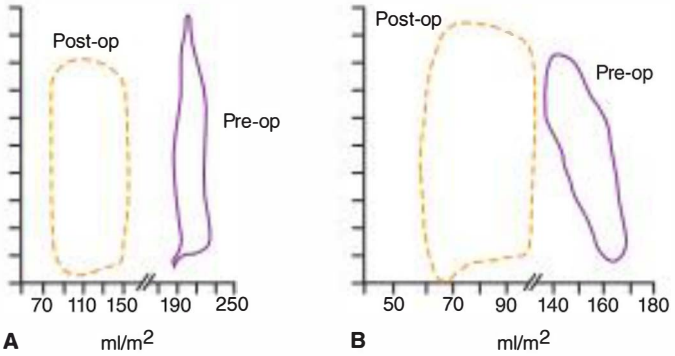

**FIGURE 52-11** Pre- and postoperative pressure volume loops. (Adapted from DiDonato M, Toso A, Dor V, et al. Surgical ventricular restoration improves mechanical ventricular dyssynchrony in ischemic cardiomyopathy. *Circulation* 2004;109:2536–2543. With permission. Copyright Elsevier.)

pressure/length (P/L) loops were created by analyzing ventriculograms utilizing the centerline method at 45 discrete intervals. The P/V loops of these patients were very abnormal in size, shape, and orientation, with impaired isometric phases and a rightward shift. Endocardial time motion was either early or late, yielding P/L loops that were abnormal in size, shape, and orientation. Postoperatively, SVR resulted in a leftward shift of the P/V loops, with their near normalization, as well as normalization of endocardial motion and P/L loops (Fig. 52-11). These physiologic results of SVR occurred in concert with improved EF (30 ± 13 to 45 ± 12 percent), reduced end-diastolic and systolic volume indices (202 ± 76 to 122 ± 48 mL/m$^2$ and 144 ± 69 to 69 ± 40 mL/m$^2$, respectively), a more rapid peak filling rate (1.75 ± 0.7 to 2.32 ± 0.7 EDV/s), peak ejection rate (1.7 ± 0.07 to 2.6 ± 0.09 Sv/s), and calculated measurements of mechanical efficiency.[21]

Schreuder and colleagues further examined the biomechanical impact of SVR on left ventricular function among nine patients who underwent this procedure.[35] Utilizing intraoperatively placed, high-fidelity conductance volume catheters, they studied pressure–volume relationships, energy efficiency, and mechanical dyssynchrony before and immediately after SVR was performed. Mean overall end-diastolic volume was reduced by 37 percent with a concomitant improvement in diastolic function with a 34 percent decrease in $-dP/dt_{max}$. Left ventricular systolic function was significantly improved as evident by a 42 percent increase in $+dP/dt_{max}$, 28 percent increase in peak ejection rate, and 16 percent increase in EF. Left ventricular dyssynchrony was decreased in both systole (33 percent) and diastole (20 percent), leading to an overall 36 percent increase in left ventricular efficiency.

There have been two reports that have specifically examined the effects of SVR on left ventricular diastolic function.[36,37] Some have raised concern that although SVR improves systolic function by eliminating noncontributory myocardium, this reduction in myocardium may lead to a restrictive physiology. The first report examined LV diastolic function in 146 patients who underwent SVR using echocardiographic measurement of transmitral flow patterns.[36] Prior to SVR, LV filling patterns were abnormal in 68 percent, pseudonormal in 19 percent, restrictive in 8 percent, and normal in only 5 percent. After SVR, they found that diastolic function was either unchanged or improved among most patients with 10 percent demonstrating improvement, 72 percent with no change, and worsened in only 18 percent of patients. Those patients with worsened diastolic dysfunction had global ventricular dilation, and those with improvement had dilation of the LV apex only. This group has recently published a longer-term study of diastolic dysfunction among these patients at a median follow-up of 7 months.[37] Again the majority of patients, 78 percent, did not demonstrate any restrictive patterns whereas 22 percent did. Multivariate analysis concluded that preexisting diastolic dysfunction prior to SVR and global dilation of the LV with increased septolateral dimensions were independent predictors of late diastolic dysfunction.

The incidence of ventricular arrhythmias following SVR has been reported by multiple groups with strikingly different results. Early series reported anywhere from a 0 to 3 percent incidence of sudden cardiac death during 5-year follow-up after SVR.[38,39] Other studies reported significant arrhythmias requiring ICD placement in nearly one third of patients who undergo SVR.[40] Two studies reported the incidence of inducible ventricular arrhythmias following SVR, with differing results.[41,42] DiDonato reported on the incidence of ventricular arrhythmias among 382 patients who underwent SVR. In this study, patients underwent preoperative as well as postoperative ventricular stimulation. Preoperatively arrhythmogenic potential was related to the size of the LV; those with LV end-systolic volume index (LVESVI) >120 mL/m$^2$, >100 mL/m$^2$, and <100 mL/m$^2$ exhibited spontaneous, inducible, and no arrhythmias, respectively. Following SVR, sudden cardiac death occurred in only 2.5 percent of patients, and among the entire group, there was an overall decrease in inducible ventricular arrhythmias from 41 percent preoperatively to 8 percent after SVR. O'Neill reported an experience with 217 patients who underwent ventricular stimulation postoperatively following SVR. His group identified significantly

more patients with postoperatively inducible ventricular arrhythmias (42 percent), but only one death attributable to sudden cardiac death. Criticisms of this study include a more rigorous arrhythmia induction protocol and lack of preoperative induction for comparison. Potential mechanisms for reductions in ventricular arrhythmias include revascularization, mechanical resynchronization, and reduction in volume with ensuing reduction in wall stress, but the impact of SVR on this aspect of post-SVR physiology is not entirely clear.

The group at the Cleveland Clinic investigated the impact of ventricular remodeling on the neuroendocrine axis following SVR. Several markers of the neurohormonal axis are elevated in CHF. This group investigated the plasma levels of norepinephrine, renin, and angiotensin II before and 1 year following SVR as well as brain natriuretic peptide before and 3 months following SVR. They found that SVR reduced norepinephrine by 56 percent, angiotensin II by 60 percent, renin activity by 56 percent, and brain natriuretic peptide by 36 percent.[43]

## OUTCOMES

There is no consensus as to the optimal treatment of ICM. Part of the reason for this is that there are no contemporary prospective randomized trials comparing similar groups of patients between medical therapy and surgical therapies for ischemic heart disease. There are an unlimited number of characteristics that any one study may not specify to ensure that the populations studied are the same as those of other studies. The presence or absence of viability, the presence of targets for revascularization, the location of infarction, and the presence of valvular disease or pulmonary hypertension are but a few making the point.

The published literature on SVR is largely retrospective and nonrandomized.[21] Much of it comes from single-center studies from institutions with a great deal of experience and some published from a limited number of multicenter studies. Although many studies can be criticized for the format, most provide some useful clinical information. A summary of the retrospective data for SVR is presented in Table 52-3.

The effectiveness of SVR can be assessed from a variety of different perspectives. Survival, morbidity, and functional outcomes are the most commonly utilized benchmarks. The optimal technique for performing SVR has not been determined. The personal beliefs of authors have been either implicitly suggested by the surgical technique utilized or studied by direct comparison, usually with a single institutional retrospective study. In a procedure whose functional outcomes are in part based on changing the size and shape of the heart, morphologic assessments are important considerations. A recent analysis of over 12,000 patients who underwent SVR from 1980 to 2005 utilizing a variety of surgical techniques was recently published by Klein et al.[44] This analysis found that endoventricular repair was associated with a reduced risk of both early- and late-term mortality compared to linear repair. Regardless of the technique employed, the addition of CABG was associated with improved outcomes and mitral valve repair with poorer outcomes in this large patient cohort. This is not surprising since most studies report that the need for mitral repair indicates a sicker patient population with advanced remodeling and larger ventricles.

### Retrospective Studies

The RESTORE group is a collection of international centers performing SVR that have combined data to study the outcomes of the SVR procedure.[45] The combined number

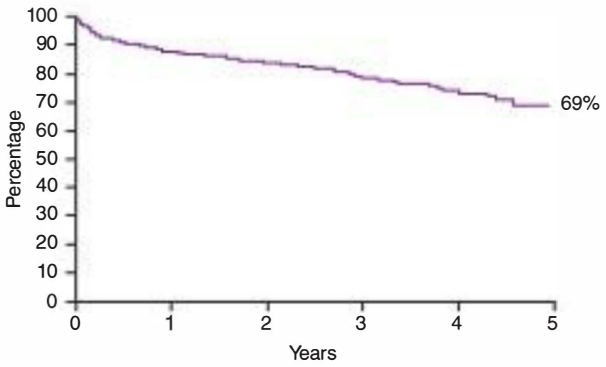

**FIGURE 52-12** Overall 5-year survival curve from the RESTORE group. (Adapted from Athanasuleas CL, Buckberg GD, Stanley AW, et al. Surgical ventricular restoration in the treatment of congestive heart failure due to post-infarction ventricular dilation. *J Am Coll Cardiol* 2004;44:1439–1445. With permission. Copyright Elsevier.)

of patients followed up by this group is 1198, operated on between 1998 and 2003. Most patients were in NYHA class 3 (40 percent) and class 4 (29 percent). Concomitant procedures included CABG in 95 percent, mitral valve repair in 22 percent, and replacement in 1 percent. This study represents what is probably the best large study to date in performing SVR in a heart failure population. The RESTORE investigators found that global systolic function increased postoperatively and ventricular size decreased as measured by ventriculography, magnetic resonance imaging, or echocardiography. The EF increased from 29.6 ± 11 to 39.5 ± 12.3 percent. The LVESVI decreased from 80.4 ± 51.4 mL/m$^2$ to 56.6 ± 34.3 mL/m$^2$. Survival was excellent in this group. Thirty-day mortality was 5.3 percent, and the overall 5-year survival was 68.6 ± 2.8 percent (Fig. 52-12). Logistic regression analysis was performed to identify risk factors for death at any time following surgery. These included preoperative EF below 30 percent, LVESVI above 80 mL/m$^2$, advanced NYHA functional class, and age above 75 years. Patients with an EF below 30 percent had a survival of 63.8 ± 3.9 percent compared to 76.7 ± 3.2 percent for those with an EF above 30 percent and 83.0 ± 4.0 percent with an EF of greater than 40 percent. The fact that many of these risk factors are the same or similar to those identified by both Menicanti and Mickleborough suggests the ability of single institutions to discover the same findings as seen in multicenter studies.

Menicanti and colleagues from Milan reported their large experience of over 1000 patients who underwent SVR. The overall operative mortality was 7.2 percent and was lower (4.8 percent) in patients who underwent concomitant CABG, and higher in patients with a preoperative EF below 30 percent (12.3 percent), with concomitant mitral valve procedures (15 percent), and in patients with NYHA class 4 symptoms (15.2 percent).[46] What is not easy to discern in this or any other single-institutional experience is exactly what the interplay of two or three of these factors is, but it is logical that the risk would be higher. These investigators have identified that factors associated with adverse outcomes include worse NYHA functional class, EF below 20 percent, age above 70 years, urgent intervention, mitral valve procedure, pulmonary hypertension (pulmonary artery systolic pressure >60 mm Hg), larger ventricles (end-diastolic volume index >180 mL/m$^2$), the number and sites of previous MIs, and right ventricular dysfunction.[19]

Mickleborough and colleagues reported on 285 patients over a 20-year period utilizing a linear closure technique with (25 percent) or without septoplasty (75 percent).[24] The excellent 5- and 10-year survival rates were 82 and 62 percent, respectively. As mentioned above, it is unclear whether the patient populations are the same. The study group included posterior infarcts and the data are presented together. In the anterior infarct group (appropriate for SVR), only 62 percent had CHF of unknown severity despite having a low EF (mean 24 + 11 percent). Patients had to have a palpably thinned area in the anterior wall, and severe mitral regurgitation was an exclusion criterion (only 1 percent had a valve intervention. Moreover, the presence of calcified aneurysms excluded some patients. Despite these differences, the risk factors for poor outcomes were EF below 20 percent, CHF, ventricular tachycardias, and hypertension—in all, not too dissimilar from the conclusions of other investigators.[22,47–49]

The group at the Cleveland Clinic have reported their decade of experience performing SVR in 220 patients.[50] NYHA class 3 or 4 symptoms were present in two-thirds of patients, and mean preoperative LVEF was 21.5 percent. Nearly half of patients underwent either mitral valve repair or replacement along with SVR. LVEF improved from 21.5 to 24.7 percent, and significant MR (>1+) was reduced from 49 to 26 percent after SVR. Perioperative 30-day mortality was 1 percent, and 1-, 3-, and 5-year overall survival rates were 92, 90, and 80 percent, respectively. Factors associated with increased mortality included EF <20 percent, BMI <24, QRS >130 ms, postoperative renal failure, and prolonged ICU stay.

Our group at Johns Hopkins has looked at the outcomes of groups of patients with severe advanced CHF. In one study, 100 percent of the patients had class 3 (34 percent) or class 4 (66 percent) CHF and an EF by magnetic resonance imaging below 20 percent, with 65 percent having an EF below 15 percent. Despite how sick these patients were, 69 percent improved to NYHA class 1 or 2, with a 1-year survival of 81 percent. Cox regression analysis demonstrated that preoperative diabetes, the use of an intra-aortic balloon pump during surgery, incomplete revascularization, and a preoperative LVESVI greater than 130 mL/m$^2$ were significant predictors of overall mortality.[49]

The Hopkins group also looked at the outcomes of SVR in patients who had multiterritory infarctions that had been contraindications in all previously published series. The finding that standard treatment of the anterior wall infarction, along with suture plication of the inferior wall for infarctions in the territory of the right coronary artery and the lateral wall for infarctions in the lateral wall opens the door to a potentially new patient population for this procedure.[22]

## Prospective Randomized Clinical Trials

With regard to the addition of SVR to conventional CABG for revascularization, there have been two recent prospective randomized clinical trials comparing revascularization with revascularization plus SVR in patients with ischemic heart disease.[12,51]

Riberio and colleagues reported on 74 patients with an EF less than 35 percent, LVESVI greater than 80 mL/m$^2$, and akinetic anterior wall motion who were randomized to either revascularization with CABG ($n = 35$) or revascularization plus SVR utilizing the endoventricular technique ($n = 39$) at a single institution.[51] Patients with significant valvular pathology were excluded with the exception of grade 1–2 MR. There were no significant differences among preoperative characteristics of either group; specifically with regard to age, LVEF, number of diseased coronary vessels, percent of LV asynergy, MR, or NYHA class. CABG was performed in a similar manner for both groups, and the only difference between the operative characteristics among groups was that the group with SVR predictably had longer CPB times. There were no differences in perioperative morbidity or mortality. Left ventricular size as measured by LVESVI immediately postoperatively and at 2-year follow-up was significantly less for those patients undergoing SVR compared to those undergoing CABG alone (62 and 65 mL/m$^2$ vs 91 and 98 mL/m$^2$, respectively). At the end of follow-up there were significant differences in outcome between the two groups. Postoperatively at the 2-year follow-up, LVEF was improved for both groups. However, the increase was greater for the group with SVR (30.5–46.5 percent vs 29.0–38.0 percent, $p < 0.001$), and over two-thirds of patients who underwent SVR had an increase of greater than 10 percent LVEF. NYHA class symptoms were improved in both groups, but the degree of improvement was greater in the CABG plus SVR group (2.3 vs 1.4, $p < 0.001$). Recurrent heart failure (26.4 vs 2.6 percent, $p < 0.001$) and severe MR (17.6 vs 0 percent, $p = 0.02$) were worse in the group who underwent CABG alone. Although there was no difference in overall mortality between the two groups, event-free time (all causes of death, MI, recurrent heart failure) following surgical intervention was significantly increased in the group who underwent CABG and SVR ($p = 0.016$). Although conducted in a randomized, controlled fashion and demonstrating a difference in outcomes, the overall number of patients in this study is quite small.

The STICH trial was an NIH-funded multicenter trial investigating the relative benefits of medical therapy, CABG, and CABG + SVR in treating ICM.[52] Hypothesis 2 of the funded study was designed to investigate the benefit of adding SVR to CABG in patients with an LVEF less than 35 percent, with revascularizable CAD, who were candidates for SVR based upon an ESVI of >60 mL/m$^2$, and with documentation of nonviability of the anterior wall. In this arm of the study, the plan was to enroll 1000 patients in 50 centers. The primary outcome was death from any cause or hospitalization for any cardiac cause. Patients with recent MI, planned PCI, significant aortic valvular pathology, and those with additional comorbidities and a life expectancy of less than 3 years were all excluded. All patients underwent CABG with particular methods at the discretion of the surgeon. SVR was performed according to surgeon preference with or without patch repair. However, the surgical therapy committee mandated that surgeons could use "any ventricular reconstruction method that consistently results in a low operative mortality, and average EF increase of ≥10 percent and an average LVESVI decrease of ≥30 percent as assessed by the 4-month postoperative CMR measurement.[52] All patients were optimally medically managed at the discretion of their primary heart failure team.

The initial findings were that there were no significant differences among preoperative characteristics in either group with respect to age, medical comorbidities, Canadian Cardiovascular Society (CCS) angina symptoms, NYHA class, LVEF, LVESVI, percent LV akinesia, MR, number of diseased coronary vessels, or heart failure medications. Thirty-day perioperative mortality was identical (5 percent) among those undergoing CABG and those with CABG plus SVR. Both groups experienced a statistically significant improvement in the CCS angina class and the 6-min walk test as well as NYHA class, but there were no statistically significant outcome differences between the CABG alone and CABG plus SVR groups. The primary outcome of death from any cause or hospitalization for cardiac reasons was similar for both the CABG and CABG plus SVR groups (59 vs 58 percent). The CABG group and CABG plus SVR groups were not different with respect to death from any cause (28 vs 28 percent), hospitalization for any cause (55 vs 53 percent) or cardiac causes (42 vs 41 percent), or subsequent MI (4 vs 4 percent). Subset analyses failed to identify any differences between the two groups and the accompanying editorial concluded that the addition of SVR to CABG for patients with ICM is not justified based upon these results.[53]

There were, however, many criticisms of the design of the study and the manner in which it was conducted.[54,55] Patient selection was a specific criticism of the study. The requirement for documentation of nonviability was dropped and the enrolled patients had to only demonstrate "dominant anterior LV dysfunction."[12] It is well known that viable muscle can demonstrate abnormal wall motion by echocardiography and the demonstration of akinesis or dyskinesis by echocardiography does not meet the threshold standard for proving nonviability.[55–57] SVR has never been recommended for patients with viable myocardium. The second major criticism concerns the adequacy of the SVR procedure. The average LVESVI reduction in this trial was only 19 percent. This degree of LVESV reduction is far less than the average of 40 percent as has been previously reported in large, nonrandomized trials of SVR, suggesting that the operations may not have been properly performed according to current practice.[55] In addition,

as reported by Michler et al. at the 2010 meeting of the American College of Cardiology in Atlanta, the majority of patients (>60 percent) had either no reduction or less than 30 percent reduction in LVESVI.[58] Patients were divided into three groups based upon echocardiographic measurement of postop LVESVI: group 1 was ≤ 60 mL/m², group 2 60–90 mL/m², and group 3 >90 mL/m². He found that in group 1 only 28 percent had an LVESVI reduction of ≥30 mL/m² with 43 percent having no reduction; 38 percent in group 2 had a reduction >30 mL/m² with 20 percent having no reduction, and 44 percent in group 3 had a reduction with 21 percent having no reduction. In addition, no patient had a 10 percent improvement in EF. This supports concerns over the quality of the surgical recommendations.

A recent study by DiDonato et al. demonstrated that postoperative LVESV is an independent predictor of survival following SVR and suggested that this may explain the lack of difference with the addition of SVR in the STICH trial.[59] To qualify as a surgeon for this study, surgeons had to demonstrate a mortality of <5 percent in 25 patients having undergone CABG in patients with an EF of <40 percent, an operative mortality of <10 percent, and an LVESVI reduction of 30 percent in 5 SVR cases.[52] There is no report that this threshold was met. Trial expansion to 127 sites due to poor enrollment led to an average of four operations per site. Critics suggest that to properly evaluate the outcome in this cohort of patients, only those patients who have documentation of nonviability and documentation of an adequate SVR procedure as defined by the STICH surgical therapy committee should be included. Until then, the STICH trial fails to answer the question in the Hypothesis 2 it was intended to answer.

## CONCLUSIONS

In summary, SVR is a procedure that has evolved from a treatment for ventricular aneurysms to become a treatment for CHF. It has been shown to improve ventricular size, morphology, LVEF, stroke-volume index, endocrine markers of CHF, ventricular energetics, ventricular synchrony, and mechanical efficiency. Clinically, it results in improved functional capacity (NYHA class) and an excellent 5-year survival in very sick patients. It is an excellent treatment option in appropriately selected patients with ICM. The results from two separate randomized clinical trials are not congruous, and future larger, well-designed studies may be necessary to determine the eventual role of SVR in the treatment of ICM. Where SVR will fit in the armamentarium of a heart failure team will be institution-dependent based on their expertise and experience. Further studies are needed to better define the appropriate patients, the basis of the beneficial response (ventricular physiology versus relief of ischemia), the optimal technique, and the appropriate time to perform the procedure. Much remains to be worked out.
